Antifungal and Antiviral Therapy

Luis Ostrosky-Zeichner | John H. Rex

CHAPTER OUTLINE

SYSTEMIC ANTIFUNGAL AGENTS

Polyenes

Flucytosine

The Azole Antifungal Agents

Echinocandins

SPECIFIC INDICATIONS AND USES FOR ANTIFUNGAL THERAPY

Candida Infections

Cryptococcosis

Aspergillosis

Histoplasmosis

Mucormycosis

Other Fungal Infections

AREAS OF CONTROVERSY IN ANTIFUNGAL THERAPY

Empirical Antifungal Therapy for the Febrile ICU Patient

Antifungal Prophylaxis in the ICU

Duration of Therapy and Accumulated Dosing

Measurement of Drug Levels

Susceptibility Testing

ANTIVIRAL AGENTS

Acyclovir, Famciclovir, and Valacyclovir

Ganciclovir and Valganciclovir

Cidofovir

Foscarnet

Amantadine and Rimantadine

Ribavirin

Oseltamivir

Zanamivir

SPECIFIC INDICATIONS AND USES FOR ANTIVIRAL THERAPY

Herpes Simplex and Varicella-Zoster

Cytomegalovirus Infections

Influenza

Other Viral Infections

Over the past 2 decades, fungal and viral diseases have become progressively more important to the critical care specialist. Increasing populations of immunocompromised hosts with serious fungal and viral infections often require critical care, and patients hospitalized in critical care units are also susceptible to these infections. Effective management of these conditions requires not only use of the appropriate anti-infective agents but in-depth knowledge of their pharmacodynamic/pharmacokinetic properties, as well as awareness of their physiologic effects, toxicities, and drug interactions. Recent years have also brought important antifungal and antiviral drug developments, giving the clinician an ever-increasing arsenal of therapeutic choices.

SYSTEMIC ANTIFUNGAL AGENTS

This chapter will focus on systemic antifungal therapy as it is relevant to the critical care setting. Topical therapy of candidiasis and therapy of other systemic fungal infections will be omitted or only briefly reviewed. The interested

reader is referred to the Infectious Diseases Society of America (IDSA) guidelines on the topic.¹

POLYENES

Polyenes act by binding to ergosterol in the fungal cytoplasmic membrane, causing ionic leakage and osmotic instability.² Additionally, they cause oxidation of the cytoplasmic membrane.² Polyenes are fungicidal in most settings and the most prominent members of the family are amphotericin B and nystatin. Both drugs have important toxic effects that often limit their use in patients with organ/system failure. Newer formulations of the drugs have been developed to reduce this limitation.

AMPHOTERICIN B AND ITS LIPID FORMULATIONS

Amphotericin B is produced by *Streptomyces nodosus* and is one of the oldest and most widely used antifungal agents. There is much experience with its use in mycoses and hosts, and it is usually the comparison standard for new therapies.³ Because of significant acute and chronic toxicities, there is

an extensive anecdotal literature describing ways to ameliorate these toxicities, as well as limitations of all these strategies.⁴ The advent of lipid-based formulations of amphotericin B has enhanced our ability to limit toxicities and provide adequate courses of therapy.⁵

Amphotericin B has in vitro and in vivo activity against most isolates of *Candida* spp., *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Mucorales*, *Coccidioides immitis*, *Paracoccidioides brasiliensis*, *Aspergillus* spp., *Fusarium* spp., and *Sporothrix schenckii*.⁶ The activity of amphotericin B is so broad that it is almost easier to think of this in terms of the few species that are consistently less susceptible or actually resistant to amphotericin B: *Aspergillus terreus*,⁷ *Trichosporon* spp.,⁸ and *Pseudallescheria boydii* (*Scedosporium prolificans*).⁹ One species of *Candida*, *C. lusitanae*, readily becomes resistant to the polyenes.¹⁰ Resistance among isolates of *Candida* is otherwise rare.^{11,12}

Amphotericin B is hydrophobic and is combined with deoxycholate to permit intravenous (IV) administration in an aqueous solvent. Once in the bloodstream, it dissociates and binds to plasma proteins and lipoproteins. It is stored in the liver and other organs and slowly eliminated. Drug metabolism is complex and not affected by renal or liver failure.³ Hemodialysis and peritoneal dialysis do not remove the drug. Measuring drug levels is possible¹³ but not of obvious clinical relevance. Cerebrospinal fluid (CSF) penetration is poor. Although amphotericin B is primarily used in IV infusion, it can also be used topically for localized gastrointestinal (GI) or urinary infections or instilled directly to treat central nervous system (CNS) infections.

The most common toxicity is the systemic reaction associated with IV infusion, thought to be caused by release of inflammatory mediators from monocytes and macrophages and producing fever, hypotension, and on occasion severe dyspnea. Two forms of renal toxicity are seen. First, a very acute form of renal dysfunction appears to be related to amphotericin B-induced renal arteriolar constriction.¹⁴ Second, cumulative dose-dependent tubular damage is almost invariably seen if significant doses are given. The tubular injury is characterized by potassium/magnesium wasting and azotemia. It is generally reversible when the drug is stopped, but it is also particularly aggravated if the patient is volume depleted or given other nephrotoxic drugs. The renal injury also reduces erythropoietin production¹⁵ and thus causes a mild anemia during chronic therapy (the hematocrit will typically fall to about 30%). Finally, amphotericin B may precipitate cardiac arrhythmias, especially if the patient is already hypokalemic and hypomagnesemic.¹⁶⁻¹⁹ The deoxycholate formulation of amphotericin B is given intravenously at 0.5 to 1.0 mg/kg/day, but it can also be administered every other day by doubling the dose. To avoid producing a precipitate, it must be diluted in an electrolyte-free solution at no more than 0.1 mg/mL. It should be administered over no less than 1 hour and most authorities prefer a 2- to 3-hour infusion.²⁰ Because the occasional patient reacts violently to the drug, an initial test dose of 1 mg of the drug may be given prior to infusing the entire first dose. Premedication with acetaminophen, diphenhydramine, and steroids may be used if the patient develops reactions to the infusion. Volume loading appears to reduce nephrotoxicity, and many authorities give (if possible) 500 to 1000 mL normal saline just

prior to each dose of amphotericin B. Administration via a central line is advisable because amphotericin B given peripherally often produces phlebitis.

Treatment goals have been traditionally and arbitrarily cumulative (such as a total of 1 or 2 g), but a time-based approach is increasingly used for some diseases (e.g., for candidemia, in which 2 weeks of therapy at 0.6-0.7 mg/kg after the last positive blood culture has been shown to produce a late relapse rate of about 1%).²¹ Although the importance of therapy in the typical patient is unclear,^{22,23} candiduria is sometimes treated with amphotericin B bladder washes. A typical dose is 50 mg of amphotericin B diluted in 1000 mL of water and irrigated over 24 hours. A small number of intracranial fungal infections benefit from intrathecal dosing at 0.1 to 0.5 mg three times per week, but expert advice should be sought if this therapy is considered.

There are three lipid-based formulations of the drug: amphotericin B colloidal dispersion (ABCD, marketed as Amphotec and Amphocil), amphotericin B lipid complex (ABLC, marketed as Abelcet), and liposomal amphotericin (L-AmB, marketed as AmBisome). The names of these compounds are often confusing. Only one of the drugs (L-AmB) is a true liposome. However, it is not uncommon for physicians to refer to therapy with these compounds in general as therapy with "liposomal amphotericin B." The preferred terminology is "lipid-associated formulation of amphotericin B" (LFAB).⁵ When speaking of specific compounds, we find that use of the names ABCD, ABLC, and AmBisome minimizes confusion.

All three LFABs have comparable efficacy among themselves and when compared to regular amphotericin B, but significantly less nephrotoxicity.^{5,24} They are also thought to be concentrated and distributed in the reticuloendothelial system, theoretically achieving higher tissue dose delivery and concentration. The lipid carrier does, however, dramatically change the pharmacology and delivery of these compounds, and higher doses than are typical for amphotericin B are both safe and necessary for optimal activity: The licensed dosages are 5 mg/kg/day (ABLC), 3 to 6 mg/kg/day (ABCD), and 3 to 5 mg/kg/day (AmBisome). The optimal dosage of these compounds is unclear and the agents appear generally equipotent. Dosages of approximately 3 mg/kg/day would appear suitable for treatment of most serious *Candida* infections. Doses of at least 5 mg/kg/day are used for mold infections, with some authors recommending even higher doses.²⁵⁻²⁷ However, a recent study showed no advantage to using 10 mg/kg/day over 3 mg/kg/day for invasive aspergillosis and other invasive mold infections.²⁸

All three LFABs appear active against the same range of fungal infections that can be treated with amphotericin B. The compounds do differ in their relative toxicities.²⁴ ABCD appears to have significant administration-related toxicity and is not often used. AmBisome and ABLC are both well tolerated, but AmBisome has been associated with somewhat less nephrotoxicity in some patient settings.²⁹ Some patients will tolerate one formulation better than another.^{30,31}

Because of the cost of the LFABs, there has been great interest in the concept of making a pseudo-LFAB by suspending amphotericin B deoxycholate in commercially

available lipid emulsions.³²⁻³⁴ This practice does not, however, consistently reduce toxicity.³⁵ This may be due to preparation-dependent precipitation of the amphotericin B noted by some^{36,37} but not all³⁸ authors. Most authorities have concluded that further work with this approach should be undertaken as part of a controlled clinical trial that addresses these issues.³⁹ A recent meta-analysis on the use of these formulations has been published, but because of heterogeneity, the results are inconclusive.⁴⁰

The cost of the LFABs is significant, but the counterbalancing reduction in nephrotoxicity is also valuable and should be considered when choosing an LFAB versus a conventional amphotericin B.⁴¹ A recent study of the impact of nephrotoxicity of amphotericin B deoxycholate in patients with invasive aspergillosis suggested that this patient population suffered significant morbidity due to the amphotericin B itself.⁴² Use of amphotericin B deoxycholate produces significant nephrotoxicity in about 30% of patients, increasing hospital length of stay and hospitalization costs by nearly \$30,000.^{43,44} Nevertheless, the context of amphotericin B-induced toxicity should also be considered. A rise of the creatinine to 3 mg/dL in an otherwise well patient who is being treated with amphotericin B for (say) osteoarticular sporotrichosis may be clinically imperceptible owing to the fact that the patient has no other acute medical problems. On the other hand, a rise in creatinine from 1 mg/dL to 2 mg/dL may be disastrous in a surgical patient who is also suffering from nosocomial pneumonia and cardiac insufficiency. No firm guidelines in this area have yet to emerge. We currently believe that an LFAB is appropriate for patients who have failed amphotericin B deoxycholate (FDA [Food and Drug Administration] indication), or who are intolerant of amphotericin B deoxycholate (FDA indication), or who are highly likely to be intolerant (no FDA indication). We define intolerance broadly: a creatinine clearance (CrCl) less than 50% of the normal for the patient's age or a fall in CrCl with therapy. Predicting intolerance is difficult, but such factors as concomitant use of highly nephrotoxic agents (e.g., an aminoglycoside) or underlying primary/intrinsic renal disease (e.g., diabetes mellitus) associated renal dysfunction should be considered.

FLUCYTOSINE

Flucytosine (5-FC) is the fluorine analog of cytosine.⁴⁵ It was originally synthesized as an antineoplastic agent, but poor antitumor activity and discovery of its antifungal properties led to its further development as an antifungal agent. It acts by deamination to 5-fluorouracil and then conversion to a noncompetitive inhibitor of thymidylate synthase that interferes with fungal DNA and RNA synthesis. It has been demonstrated effective in cryptococcosis, candidiasis, and chromomycosis, being the drug of choice for the latter infection. Drug resistance *in vivo* develops quickly, so the standard practice is to combine it with another agent.^{46,47} 5-FC is water soluble and has high bioavailability. Protein binding is negligible and approximately 90% is excreted in urine. CSF penetration is good, and both hemodialysis and peritoneal dialysis remove it. It is teratogenic in rats and therefore contraindicated during pregnancy. Adverse effects include rash, diarrhea, and hepatic dysfunction. High blood levels (>100 µg/mL) are associated with profound

leukopenia and thrombocytopenia.⁴⁸ This has prompted the recommendation of monitoring drug levels, renal/liver function, and blood counts in patients receiving 5-FC. Dosage of 150 mg/kg/day divided in four doses has usually been suggested, but recent *in vivo*⁴⁹ and human experience⁵⁰ suggests that dosage of 100 mg/kg/day (again, divided into four doses) may be as effective and better tolerated. Renal failure requires dosage adjustment to half the dose if CrCl is 25 to 50 mL/minute and a quarter dose if it falls below 25 mL/minute. Patients on hemodialysis should be given the latter dose after dialysis. Combination with amphotericin requires constant monitoring of toxicity parameters and dose adjustment. The target blood level is approximately 50 µg/mL. Most experts would discontinue use of this agent if blood counts start dropping, regardless of the blood levels.

THE AZOLE ANTIFUNGAL AGENTS

The introduction of this class of drugs was a major advance in antifungal therapy, because they offer both IV and oral formulations for the treatment of systemic mycosis. Their widespread use has also prompted the emergence of resistance. Azoles act by blocking the activity of lanosterol demethylase, a cytochrome enzyme in both fungal and mammalian cells. Fungal cell membrane synthesis of ergosterol is inhibited and other sterol intermediates are substituted in the membrane, resulting in a nonviable cell. This effect is much slower than that of amphotericin, so these drugs are generally regarded as fungistatic. Because these drugs reduce production of the ergosterol to which polyenes must bind to produce their effect, there is a potential for the azoles and polyenes to appear antagonistic. However, these effects are drug-, organism-, and model-dependent and a range of effects may be seen. This area is complex and has recently been reviewed.^{51,52} At present, use of such combinations should be avoided outside a clinical trial. All of the azoles have the ability to interfere with mammalian sterol synthesis. This was most notable with ketoconazole, which can produce gynecomastia and adrenal insufficiency.^{53,54} Subsequent azoles have been selected for lack of such effects. All of the azoles can, however, produce hepatic dysfunction. The most common pattern is that of increased transaminases. However, any form of dysfunction may be seen. This can be life-threatening if not recognized. The hepatic dysfunction is reversible upon discontinuation of the offending azole.

Another concern with azoles is drug interactions. This becomes particularly important in the critical care setting in which many drugs are being used concomitantly. [Table 52.1](#) summarizes the most important drug interactions that have been reported. The critical interactions generally have to do with drugs cleared by the liver. Some agents (e.g., rifampin and phenobarbital) induce the enzymes that clear the azoles. In other cases, the azole interferes with clearance of another agent (e.g., the azoles predictably increase blood levels of cyclosporine). It is not possible to list all of the known interactions. Consultation with a pharmacy specialist is suggested when using azoles in the setting of polypharmacy, particularly in the critical care setting and when caring for patients with multiple comorbid conditions.

Table 52.1 Selected Azole-Drug Interactions*

Azole Drug	Alters Levels of:	Levels Altered by:	Azole Drug	Alters Levels of:	Levels Altered by:
Fluconazole	Cisapride	Rifampin	Voriconazole	Sirolimus	Rifampin
	Cyclosporine			Rifabutin	Efavirenz
	Diazepam			Efavirenz	Rifabutin
	Glipizide			Ritonavir	Ritonavir
	Glyburide			Terfenadine	Carbamazepine
	Midazolam			Astemizole	Phenytoin
	Phenytoin			Cisapride	
	Rifabutin			Pimozide	
	Sulfonylureas			Quinidine	
	Tacrolimus			Cyclosporine	
	Terfenadine			Methadone	
	Warfarins and coumarins			Tacrolimus	
				Phenytoin	
				Warfarin	
Itraconazole	Astemizole	Carbamazepine	Posaconazole	Omeprazole	
	Cisapride	Didanosine (DDI)		Sirolimus	Efavirenz
	Cyclosporine	Histamine H ₂		Tacrolimus	Rifabutin
	Diazepam	blockers		Cyclosporine	Phenytoin
	Digoxin	Phenobarbital		Pimozide	Cimetidine
	Dihydropyridines	Phenytoin		Quinidine	Esomeprazole
	Lovastatin	Proton pump		Simvastatin	Metoclopramide
	Methylprednisolone	inhibitors		Ergot alkaloids	
	Midazolam	Rifabutin		Midazolam	
	Phenytoin	Rifampin		Ritonavir	
	Quinidine	Sucralfate		Atazanavir	
	Ritonavir			Vinca alkaloids	
	Sulfonylureas			Calcium channel blockers	
	Terfenadine			Digoxin	
	Vinca alkaloids			Glipizide	
	Warfarins and coumarins				

*Generally, azoles tend to increase the levels of other drugs, whereas other drugs tend to decrease the level of the azole. This list is not meant to be comprehensive, and the practitioner should review the full prescribing information. Consultation with a pharmacy specialist is recommended when azoles are going to be used in complex polypharmacy situations.

FLUCONAZOLE

Fluconazole is one of the newer triazoles that has in vitro and in vivo activity mainly against yeast, such as *Candida* spp. and *Cryptococcus neoformans*. It also has efficacy against *Coccidioides immitis*, *Histoplasma capsulatum*, and *Blastomyces dermatitidis*. Unfortunately resistance (mediated by increased production of target enzymes, efflux pumps, and mutations in target enzyme) has become a problem, particularly in *Candida albicans* (mutation to resistance is seen), *C. glabrata* (has intrinsically lower susceptibility and may become highly resistant), and *C. krusei* (intrinsically highly resistant).^{55,56}

Nevertheless, fluconazole is still very active against most strains causing invasive candidiasis, and higher doses can be used for those organisms that are in the “susceptible-dose dependent” range. Fluconazole is water soluble and is available in oral and IV presentations that produce similar blood levels. Bioavailability is excellent and it is well absorbed regardless of the gastric contents. It has a long half-life and can be administered in a single daily dose. It exhibits little binding to serum proteins and is widely distributed in all body fluids. CSF penetration is particularly high, making it particularly useful in the treatment of CNS infections such as cryptococcosis and coccidioidomycosis. Fluconazole is

excreted by the kidneys and dosing should be adjusted in proportion to the CrCl. The most common adverse effects are nausea and vomiting. Skin rash is infrequent but can be severe. Hepatitis has also been reported. The usual dose is 400 to 800 mg (or 6-8 mg/kg) per day by mouth or IV, but doses as high as 2 g/day have been tolerated.⁵⁷

ITRACONAZOLE

Itraconazole is a triazole antifungal agent with a wider spectrum than fluconazole. It has in vitro and in vivo activity against *Candida* spp., *Aspergillus* spp., *Histoplasma* spp., *Blastomyces dermatitidis*, *Sporothrix schenckii*, *Trichophyton* spp., *Cryptococcus neoformans*, *Coccidioides immitis*, and *Paracoccidioides brasiliensis*.^{58,59} The resistance issues observed for fluconazole are also an issue with itraconazole.⁵⁶ Itraconazole was initially available only in a capsule form that has unpredictable bioavailability. Absorption of the capsule formulation is optimized by ingestion with food.⁶⁰ Two new formulations have recently been introduced. First, there is a solution in cyclodextrin for oral administration that significantly enhances bioavailability and is now preferred over the capsule for producing maximal blood levels.⁶¹ Second, an IV formulation (again, in a cyclodextrin carrier) has recently

become available. The IV formulation is valuable in that it quickly and reliably produces significant blood levels.⁶²⁻⁶⁴ Itraconazole is highly protein bound and has a prolonged half-life. CSF penetration is negligible, so it is not generally used for CNS infections. Itraconazole is metabolized by the liver and dosing does not need to be modified in renal failure. However, the cyclodextrin carrier used in the IV formulation is cleared by the kidneys and its behavior in patients with renal dysfunction is not known. Thus, this formulation of itraconazole should not be used in patients with a CrCl less than 25 mL/hour.

Adverse effects are mainly GI, with nausea, vomiting, and abdominal pain occurring in up to 10% of patients. Hepatitis is uncommon but liver enzyme monitoring is recommended. Because itraconazole, and its major metabolite hydroxyitraconazole, are inhibitors of CYP3A4, drug interactions are a major issue and the most common ones are summarized in Table 52.1.

The usual oral dosage is 100 to 400 mg/day and the oral solution formulation is now preferred. Giving the daily oral dose as two divided doses appears to maximize blood levels. IV dosing is 200 mg twice a day for 2 days and then 200 mg IV every day for a maximum of 14 days. Efficacy is related to plasma concentration, and serum levels can be obtained from national reference laboratories. Such testing is warranted if oral itraconazole is being used to treat a serious fungal infection. Although minimal efficacious blood levels have not been defined, the point of testing is to ensure that at least some level is being obtained. Levels of at least 250 ng/mL are desirable.

VORICONAZOLE

Voriconazole is one of the newest triazoles to arrive into the market. It is licensed for the treatment of invasive candidiasis and invasive aspergillosis, as well as for the treatment of *Fusarium* and *Scedosporium* infections. It is considered as the treatment of choice for invasive aspergillosis.⁶⁵ Voriconazole was not inferior to amphotericin B followed by fluconazole in a large clinical trial, but it is unknown if it has any advantages over fluconazole or the echinocandins for treating infections by fluconazole-resistant *C. glabrata*.^{66,67} Although it has activity against the endemic mycoses, data are limited at this point, so it is not recommended for routine use in these infections at this time.^{68,69}

A relevant gap in its activity is the class of Zygomycetes (such as *Mucor* spp., *Absidia* spp., and *Rhizopus* spp.). Although there have been multiple reports of breakthrough Zygomycetes infections in patients receiving voriconazole prophylaxis or treatment, a causal relationship has not been established.^{70,71} Nevertheless, clinicians should be aware that this drug does not have activity against these organisms, and thus it should not be used for empirical therapy of mold infections if Zygomycetes are in the differential diagnosis.

Voriconazole is available in oral (tablets and suspension) and IV formulations, with 96% bioavailability. Usual dosing is 4 to 6 mg/kg IV every 12 hours or 200 to 300 mg orally every 12 hours. Voriconazole has nonlinear pharmacokinetics; thus, increasing the dose will not necessarily increase blood levels. Routine blood level measurement to document absorption is now recommended, although blood levels associated with specific efficacy and safety margins

have not been established. Voriconazole is metabolized by the human hepatic cytochrome P-450 enzymes, CYP2C19, CYP2C9, and CYP3A4, and has extensive drug interactions with many drugs commonly used in the critical care setting. Consultation with a pharmacy specialist is recommended for patients on multiple drugs. Like itraconazole, the IV formulation is prepared in a cyclodextrin-based formulation, and thus it is not recommended for use in patients with CrCl less than 50 mL/minute. In such patients the oral formulation may be safely used. Adverse events include self-limited visual disturbances and hallucinations, infrequent reports of hepatic insufficiency, and as with the other azoles, rare reports of arrhythmias and QT prolongation. Monitoring of liver enzymes is recommended during voriconazole therapy.⁷²⁻⁷⁴

POSACONAZOLE

Posaconazole is the newest triazole in the market and although licensed primarily for prophylaxis of fungal infections in high-risk patients,⁷⁵ it does have promising activity against mold infections, in particular infections by the Zygomycetes and *Fusarium*.⁷⁶ It has also shown excellent in vitro and in vivo activity against *Candida* spp. with demonstrated efficacy in esophageal disease. It is available only in an oral formulation.^{77,78}

ECHINOCANDINS

The echinocandin antifungal agents represent an entirely new class of antifungal drugs. There are three echinocandins on the market at this time: caspofungin, micafungin, and anidulafungin. These agents are cyclic lipohexapeptides that act via inhibition of glucan synthesis.⁷⁹ Preclinical studies have shown efficacy against all species of *Candida* without any evidence for cross-resistance with polyenes or azoles, *Aspergillus* spp., and selected other fungi.^{80,81} Although the target enzyme is present in most fungi, the echinocandins are not active against *C. neoformans* and molds other than *Aspergillus*. The echinocandins appear to be rapidly fungicidal for *Candida* spp., but their activity against *Aspergillus* may be better described as fungistatic.⁸² Nonetheless, they are quite active in animal models of both candidiasis and aspergillosis.^{83,84} These drugs have a long half-life, permitting once-daily dosing, and are excreted in the liver. They do not interfere with the cytochrome system and they are not known to be nephrotoxic, having otherwise remarkable safety profiles. At this time, differences between the three drugs appear to be subtle, requiring further study.

CASPOFUNGIN

Caspofungin was the first echinocandin in the market. It has excellent in vitro and in vivo activity against *Aspergillus* and *Candida* spp. It has demonstrated efficacy for the treatment of invasive candidiasis, treatment of invasive aspergillosis, and empirical therapy of fungal infections in the setting of febrile neutropenia.⁸⁵⁻⁸⁷ The usual dosing includes loading with 70 mg IV, followed by 50 mg IV every 24 hours. The safety profile is good with mild elevation of liver enzymes. Patients with hepatic insufficiency (Child-Pugh class B or C) require dosage adjustment to 35 mg/kg IV every 24 hours.^{68,88,89} Drug interactions are infrequent, but it is

recommended to monitor cyclosporine levels in patients receiving caspofungin.⁹⁰ A recent clinical trial showed that higher doses of caspofungin (100 mg/day) are well tolerated but do not necessarily translate into additional clinical benefits.⁹¹

MICAFUNGIN

Micafungin is approved by the by the FDA for the treatment of esophageal candidiasis, prophylaxis of *Candida* infections in stem cell transplant patients, and treatment of candidemia. Although micafungin has excellent in vitro and in vivo activity against *Aspergillus* and *Candida* spp., clinical data on invasive aspergillosis are limited.^{92,93} Micafungin has demonstrated efficacy both for the treatment of invasive candidiasis and as a prophylactic agent for fungal infections in allogeneic stem cell transplant recipients.⁹⁴⁻⁹⁶ The prophylactic dose is 50 mg IV every 24 hours, and the therapeutic dose for invasive candidiasis is 100 mg IV every 24 hours. As with the other echinocandins, the most frequent adverse event is mild elevation of liver enzymes. No dosage adjustment is required in the setting of renal insufficiency or moderate hepatic insufficiency. Mild drug interactions have been reported with concomitant use of sirolimus and nifedipine.

ANIDULAFUNGIN

As with the other echinocandins, anidulafungin has excellent in vitro and in vivo activity against *Aspergillus* and *Candida* spp.⁹⁷ It is currently indicated for the treatment of

invasive candidiasis, having demonstrated noninferiority, and perhaps superiority, in a clinical trial versus fluconazole.⁹⁸ The usual dosing includes a loading dose of 200 mg IV, followed by 100 mg IV every 24 hours. Anidulafungin does not require dosage adjustment for patients with renal or hepatic failure and no significant drug interactions are reported.^{97,99,100}

SPECIFIC INDICATIONS AND USES FOR ANTIFUNGAL THERAPY

Although the precise diagnosis of a fungal infection may be laborious, time-consuming, and delayed, therapy should never be withheld in a critically ill patient with suspected or confirmed fungal infection. Empirical therapy will often be started with amphotericin B or one of its lipid preparations and then tailored according to the final identification of the organism. This section presents generally accepted treatment recommendations for the most commonly encountered fungal infections in the critical care setting. Infections by less common fungi may be particularly severe and rapidly progressive and require consultation with an infectious diseases specialist for appropriate treatment. Table 52.2 summarizes the most often encountered fungal diseases in the critical care setting with their generally accepted treatment options. Figure 52.1 presents our approach for the critically ill patient with fungemia.

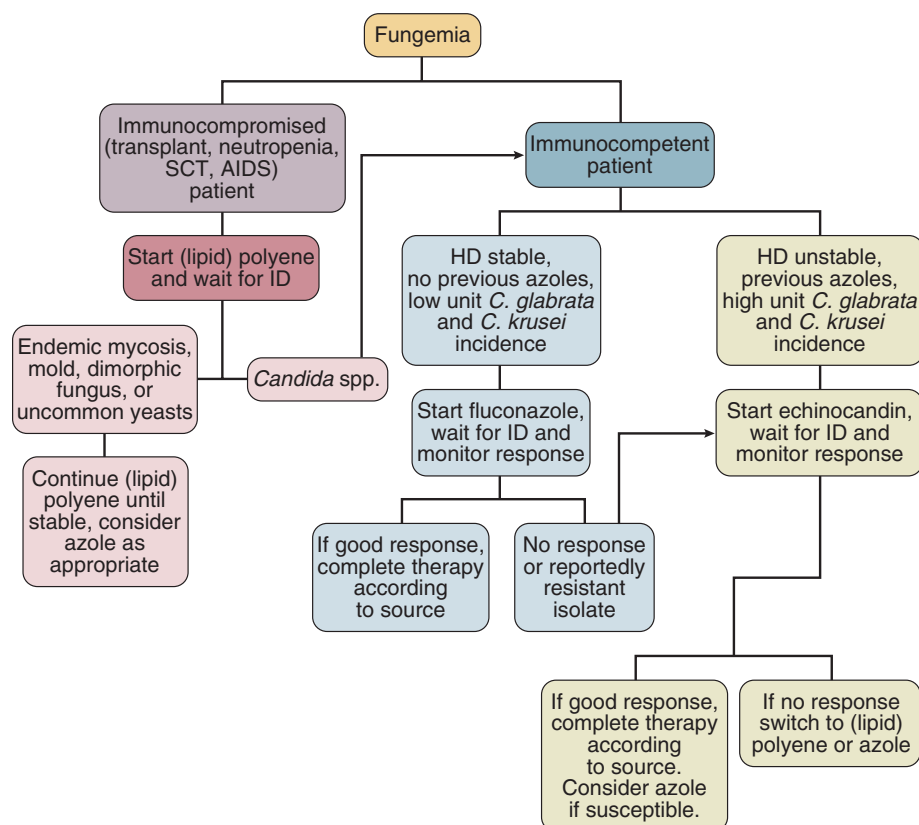

Figure 52.1 Treating the critically ill patient with fungemia. HD, hemodynamically; ID, identification to species level; SCT, stem cell transplant. (Modified from Ostrosky-Zeichner L, Pappas PG: Invasive candidiasis in the intensive care unit. Crit Care Med 2006;34:857-863.)

Table 52.2 Summary of Therapeutic Choices for Fungal Diseases Most Commonly Encountered in the Critical Care Setting

Fungal Disease	Therapy of Choice	Alternative Therapy	Duration of Treatment	Comments
Candidiasis				
Oral candidiasis	Nystatin 200,000-U lozenges qid or 500,000-U suspension swish and swallow qid	Fluconazole 200 mg single dose or 100 mg/day PO	3-5 days	
Mucosal nonoral candidiasis	Topical azole	Fluconazole 200 mg first dose, then 100 mg/day	7-14 days	
Candidemia and most forms of disseminated candidiasis	Amphotericin B 0.5-0.6 mg/kg/d or lipid preparation of amphotericin B 3 mg/kg/d; fluconazole 400 mg qd; voriconazole 4-6 mg/kg/q12h; caspofungin 50 mg/d; anidulafungin 100 mg/d; or micafungin 100 mg/d		14 days after bloodstream clearance for uncomplicated candidemia; until resolution of sites of infection if disseminated	Line removal recommended Assess for dissemination A candidin or lipid amphotericin B usually preferred for initial therapy if patient is unstable or infected with a non- <i>albicans</i> species Loading doses recommended for caspofungin and anidulafungin
Urinary candidiasis	Fluconazole 200 mg first day, then 100 mg/day or amphotericin B 0.3 mg/kg IV single dose	Amphotericin B bladder washes, 50 mg/1000 mL H ₂ O in continuous irrigation for 2 days	7-14 days	Asymptomatic funguria does not require treatment but may be a sign of dissemination in compromised hosts Urinary catheter removal is very useful
Peritonitis	As for disseminated candidiasis			Removal of dialysis catheter is helpful Surgical débridement if abscess present
Aspergillosis	Voriconazole 4-6 mg/kg/q12h	Lipid preparation of amphotericin B 3 mg/kg/d	Until resolution of the clinical process and of any associated immunosuppression	May require surgical treatment
Histoplasmosis	Amphotericin B 0.5-1 mg/kg/d or liposomal amphotericin B 5 mg/kg/d	Itraconazole 200-400 mg/d	3-12 months	Lifelong suppression needed in HIV-infected patients
Cryptococcosis (in HIV-infected patients)	Amphotericin B 0.5-0.7 mg/kg/d or lipid preparation of amphotericin B 3-5 mg/kg/d + 5-FC induction 25 mg/kg/q6h, fluconazole 400 mg/d maintenance	Induction with fluconazole 400 mg/d in stable patients	Managed very differently in HIV-infected (lifelong therapy needed) and uninfected patients (cure is possible) Expert consultation advised	Consider frequent LP to relieve intracranial pressure V-P shunts may be necessary
Zygomycosis	Amphotericin B 0.8-1.5 mg/kg/d or lipid preparation of amphotericin B 3-5 mg/kg/d + surgical débridement + metabolic control	Consider polyene + caspofungin Limited experience with posaconazole		Surgical débridement is critical

5-FC, 5-flucytosine; HIV, human immunodeficiency virus; LP, lumbar puncture; V-P, ventriculoperitoneal.

CANDIDA INFECTIONS

Although *C. albicans* remains the most common pathogen in oropharyngeal and cutaneous candidiasis, non-*albicans* species of *Candida* are increasingly frequent causes of invasive candidiasis.¹⁰¹ Guidelines and reviews for therapy of candidiasis in the intensive care setting have recently been published.¹⁰²⁻¹⁰⁵ These guidelines are extensive and will not be repeated in detail. Rather, the text will focus on several clinical situations in which candidal infections are particularly challenging for the critical care specialist.

CANDIDEMIA AND DISSEMINATED CANDIDIASIS

The diagnosis of disseminated candidiasis is always a challenge.¹⁰⁶ There is no single tool that conclusively makes this diagnosis. Isolation of *Candida* from the bloodstream is simply the most obvious form of disseminated candidiasis, but clinical experience makes it obvious that disseminated candidiasis can occur in the absence of detectable fungemia.

Candidemia may be treated initially with either fluconazole, voriconazole, amphotericin B (or its lipid preparations), or an echinocandin. In the critically ill and unstable patient, an echinocandin or amphotericin B lipid preparations is preferred because of the broader spectrum of activity and more rapid onset of action.^{104,107} Owing to their greater safety, echinocandins are increasingly viewed as the initial agents of choice, and in fact, both the anidulafungin study and recent patient level meta-analysis of the candidemia clinical trials suggest that initial therapy with echinocandins may be superior to initial therapy with azoles.^{98,108}

The susceptibility of *Candida* to the currently available antifungal agents can generally be predicted if the species of the infecting isolate is known.^{10,12,101,109-117} Bloodstream isolates of *C. albicans*, *C. tropicalis*, and *C. parapsilosis* are generally susceptible to fluconazole and amphotericin B. Isolates of *C. glabrata* and *C. krusei* will often (if not always, as is the case with *C. krusei*) be resistant to fluconazole. Isolates of *C. lusitanae* may be resistant to amphotericin B. Antifungal susceptibility testing is becoming increasingly important as a guide in the treatment of these infections.¹¹⁸ In particular, detection of fluconazole resistance is very valuable, as it provides support for continued use of echinocandins or polyenes.

Although all *Candida* spp. are generally considered to be susceptible to echinocandins, *C. parapsilosis* has higher minimum inhibitory concentrations (MICs) than the other *Candida* spp. This, however, has not translated into reduced activity in clinical trials.^{85,119} Once the organism is speciated, or if the prevalence of more resistant species is low, therapy may be switched to fluconazole. Fluconazole has demonstrated to be as effective in clearing candidemia as amphotericin B in immunocompetent hosts. Duration of treatment is 14 days following the last positive culture,²¹ and if a central line is present, removal is highly recommended. If evidence of disseminated candidiasis is found, therapy should be prolonged to at least 4 weeks to ensure proper organ clearance.

THE INTRAVENOUS CATHETER IN CANDIDEMIC PATIENTS

Although long an area of contention, current data strongly suggest that candidemia is often related to (if not primarily

propagated by) a central venous catheter. Central venous catheters in particular have been found to be both a risk factor for developing candidemia¹²⁰⁻¹²³ and associated with persistent fungemia.¹²¹ Removal of the catheter has been associated with shorter duration of subsequent candidemia¹²⁴ and improved patient outcome.^{125,126} Unique to the species of *Candida*, candidemia with *C. parapsilosis* is almost always due to a catheter.^{127,128} The situation may be different for neutropenic patients, particularly those who have permanent, lower-risk catheters such as Hickman catheters. Such catheters may of course become infected, but these patients may also have candidemia due to entry of the organisms from the gut into the bloodstream. This concept is supported by demonstrations that *Candida* can enter the bloodstream from the gut,¹²⁹ by the relative lack of effect of catheter removal in a large cohort of cancer patients,¹²⁸ and by the frequent demonstration of gut wall invasion in patients who die with disseminated candidiasis.^{130,131} Unfortunately, there is no convincing way to tell if a given catheter is involved. Differential quantitative blood cultures through the line and from a peripheral site have been suggested to be one approach to resolving this problem,¹³² but this technique remains controversial.¹³³ On a practical basis, serious consideration to line removal should be given if fungemia persists for more than a few days. A recent patient level meta-analysis of the major candidemia clinical trials has confirmed a mortality rate reduction and microbiologic cure benefit for this approach.¹⁰⁸

MUCOSAL INFECTIONS AND COLONIZATION

Although there are many risk factors for development of disseminated candidiasis, colonization at one or more non-sterile sites represents an unusually strong risk factor.¹³⁴ As discussed earlier, local oral and mucosal candidiasis should thus be considered as a predictor of possible invasive disease in the critically ill or immunocompromised host.^{135,136} Esophageal candidiasis does require systemic treatment. Fluconazole is generally preferred here, although amphotericin B and the candins can also be used.

CANDIDURIA

Treatment of asymptomatic candiduria produces only temporary clearing of the urine and is probably not indicated.^{22,23} However, candiduria should probably be treated in symptomatic patients, immunocompromised patients, low-birth-weight infants, renal transplant patients, and patients who will undergo urologic manipulation or surgery.¹⁰² If treatment is indicated, systemic therapy with amphotericin or fluconazole is preferred, and amphotericin bladder washes should be reserved for patients with renal insufficiency and low renal clearance. Removal of the urinary catheter is by itself a useful intervention and should always be considered.

OTHER FORMS OF INVASIVE CANDIDIASIS

There are many other possible forms of invasive candidiasis: meningitis, endocarditis, and osteomyelitis, just to name a few. This area has recently been reviewed,¹⁰³ and for most forms of this disease there are very few specific studies on therapy. The largest body of data will always be anecdotal reports of use of amphotericin B, and for essentially every form there are at least a few reports of successful therapy

with fluconazole. In general, amphotericin B is preferred when the infection is most acute, when data on the nature of the infection are still being generated in the laboratory, or when the patient has previously received azole therapy. Fluconazole provides a good way to step down to an oral agent to complete therapy of infections due to susceptible isolates. Data for the echinocandins are starting to accumulate for these chronic infections.¹³⁷ Removal of foreign body and standard surgical drainage are often key as well. An excellent example of the need to remove foreign bodies is found in treatment of dialysis catheter-related peritoneal candidiasis in which catheter removal is important. Surgical drainage is of course important in candidal peritonitis related to gut injury and fecal spillage.

CRYPTOCOCCOSIS

Treatment of cryptococcosis has recently been reviewed.^{138,139} Cryptococcal meningitis in non-human immunodeficiency virus (HIV)-infected adults continues to be seen sporadically. The majority of the published experience as to treatment is with amphotericin B given for 4 to 6 weeks.^{140,141} Because this therapy is curative in approximately two thirds of patients, this approach is warranted. Expert consultation is also appropriate for this relatively uncommon infection.^{142,143}

On the other hand, cryptococcal meningitis in the HIV-infected patient is a well-established and common problem. Meningeal cryptococcosis in this setting should be treated with a 2-week course of IV amphotericin B or its lipid preparations,^{139,144,145} followed by life-long suppression with fluconazole.^{146,147} Current trends favor also using 5-FC unless there is a contraindication.⁵⁰ Although itraconazole does not penetrate the CSF, anecdotal evidence has shown that it may be useful in treating CNS disease, although it is apparently less potent as a long-term therapy.¹⁴⁸

For all forms of cryptococcal meningitis, intracranial hypertension should be aggressively treated with repeated lumbar punctures or a CSF shunt.^{149,150} The addition of steroids and other immune modulating agents to antifungal therapy has shown promising results in animal models,¹⁵¹ and clinical trials are being conducted. The immune reconstitution syndrome plays a major role in cryptococcal-related morbidity in HIV patients and the current recommendation is to delay antiretroviral therapy for a few weeks after treatment for cryptococcosis is started.¹³⁹

ASPERGILLOSIS

Treatment of aspergillosis has been extensively reviewed.¹⁵²⁻¹⁵⁴ Invasive aspergillosis should be considered in any severely immunocompromised patient with an unexplained pulmonary or sinonasal process. Biopsy is normally required for definitive diagnosis, although a new generation of galactomannan-based serodiagnostic tests may prove useful as adjuncts to diagnosis.^{155,156} Although amphotericin B has classically been the initial treatment of choice for invasive aspergillosis, the current treatment of choice is voriconazole^{65,74} or a lipid preparation of amphotericin B. Aggressive surgical management is necessary and curative in some

cases.^{106,157} Itraconazole has historically been an option for the treatment of aspergillosis in patients who are intolerant or refractory to amphotericin B, but newer and more effective azoles are now available.¹⁵⁸ Overall, the outlook for invasive aspergillosis is critically dependent on recovery of immune function. Without this, the prognosis is usually dismal. Of note, recent studies have documented an increase in incidence of invasive aspergillosis in nonhematology, nontransplant patients seen in the intensive care unit (ICU), such as chronic obstructive pulmonary disease and autoimmune diseases.^{159,160} This trend should be monitored, and the critical care specialist should be suspicious when cultures of *Aspergillus* from a bronchoalveolar lavage or diagnostic markers such as galactomannan are positive.¹⁶¹

HISTOPLASMOSIS

The initial treatment of choice for severe acute histoplasmosis is an amphotericin B preparation.¹⁶²⁻¹⁶⁴ Noncritical cases may be treated with itraconazole 200 to 400 mg/day. Fluconazole is only moderately effective and should not be used as primary therapy.¹⁶⁵ Successful treatment results in a decrease of serum and urine *Histoplasma* antigen.¹⁶⁶ Duration of therapy is a function of disease form and underlying immune status. HIV-infected patients with disseminated disease should be treated as acute histoplasmosis and maintained on life-long suppression with itraconazole. Liposomal amphotericin B has shown excellent efficacy in this setting.¹⁶⁷ Non-HIV-infected patients may require from 3 to 12 months of therapy, and expert consultation is generally advised.

MUCORMYCOSIS

The treatment of choice for mucormycosis (infections typically caused by *Mucor* spp., *Rhizopus* spp., and *Absidia* spp.) is aggressive surgical débridement and prompt start of high-dose amphotericin B or a lipid preparation.¹⁶⁸ Follow-up therapy with itraconazole may be warranted, and expert consultation is advised. Posaconazole has shown efficacy in this setting.⁷⁸ More recently, and despite the lack of in vitro activity of echinocandins against these agents, investigators have shown in vitro synergy and excellent clinical outcomes with the combination of amphotericin B and caspofungin.¹⁶⁹ Correction of metabolic abnormalities (acidosis, iron overload, and hyperglycemia) should also be pursued aggressively.

OTHER FUNGAL INFECTIONS

Other fungal infections, such as blastomycosis, fusariosis, and infection by *Trichosporon* spp., *Coccidioides immitis*, *Malassezia furfur*, and *Penicillium* spp. may be occasionally encountered in the critical care setting, particularly when caring for immunocompromised hosts. Although amphotericin B is probably the best empirical drug for any characterized suspected fungal infection, it is not very effective against some of these pathogens. Guidelines for treating some of these infections have been published.¹ Expert consultation should be promptly obtained.

AREAS OF CONTROVERSY IN ANTIFUNGAL THERAPY

EMPIRICAL ANTIFUNGAL THERAPY FOR THE FEBRILE ICU PATIENT

Fever in the ICU patient is a complex problem that requires prompt evaluation for many possible sources, including infection, atelectasis, pulmonary embolism, drug fever, thermoregulatory dysfunction, and many more.¹⁷⁰ Infection by *Candida* should be suspected when the patient has risk factors such as immunocompromise, broad-spectrum antibiotic therapy, parenteral nutrition, steroids, surgery (especially if the gut wall is transected), urinary catheters, and burns.^{171,172}

Unfortunately, making a diagnosis of invasive candidiasis is difficult. In the most straightforward scenario, the patient is febrile and has positive blood cultures for *Candida*. On other occasions, biopsy or aspiration is used to make a clear-cut diagnosis of a localized abscess due to *Candida*. These situations are, however, the exception. Far more common is the scenario of a persistently febrile ICU patient with a combination of the previously mentioned risk factors. In this setting, we place great importance on the presence of positive cultures from nonsterile sites such as wounds, sputum, or stool. The key concept is that presence of *Candida* at any of these sites significantly increases the likelihood of developing invasive disease.^{134,173} Positive cultures from the urine are also considered in this context (even though that is normally a sterile site). Candiduria in the afebrile patient is generally a clinical non-event that does not require therapy,^{22,23} but candiduria in the febrile ICU patient at the very least represents colonization and increased risk of invasive disease and at the worse represents actual upper urinary tract infection. A similar logic applies to *Candida* in the sputum. Pneumonia due to *Candida* occurs but is generally clinically inapparent.¹⁷⁴ The presence of *Candida* in the sputum more often means that the gut, and thus the patient, is colonized. This, in turn, is a risk factor as discussed previously.

Research has shown conclusively that delays to appropriate antifungal therapy in ICU patients with invasive candidiasis are associated with increased mortality rates.¹⁷⁵ The latest version of the IDSA guidelines recommend empirical antifungal therapy in critically ill patients who are deemed to be at high risk for the infection based on a variety of recently available scoring systems and risk assessment strategies.^{105,176-180} On the other hand, there is a negative multicenter study that failed to show a benefit to fluconazole in this setting.¹⁸¹

ANTIFUNGAL PROPHYLAXIS IN THE ICU

Prevention is always preferred to therapy, and this is certainly true for invasive candidiasis. Although prevention of mucosal disease can be achieved with almost any regimen, prevention of invasive disease has consistently required systemic therapy. Both fluconazole and amphotericin B are effective in the right setting. The key is to select patient

populations with a meaningful chance of contracting invasive candidiasis. The value of prophylaxis has been shown convincingly for bone marrow transplantation patients^{182,183} and selected liver transplant patients.¹⁸⁴⁻¹⁸⁷ Studies of patients receiving standard chemotherapy for leukemia have shown a trend favoring prophylaxis,^{188,189} but the lower rates of disease in the control group lower the statistical power of the studies. To further confuse matters, even a group that sounds homogeneous (e.g., allogeneic bone marrow transplant recipients) really is not—different forms of chemotherapy and degrees of graft-versus-host disease produce different levels of risk. This point was driven home in an editorial emphasizing the range of variation within the category of “neutropenic patient.”¹⁹⁰

In practical terms, three major studies have demonstrated benefits to prophylaxis of invasive candidiasis in the ICU.¹⁹¹⁻¹⁹³ No study or meta-analysis has shown benefits in terms of mortality rates, however.¹⁹⁴⁻¹⁹⁷ These studies have the limitation of being single center studies and having limited numbers of patients. Most experts would agree with the fact that routine use of antifungal prophylaxis should be reserved for units with a high incidence of invasive candidiasis or for carefully selected patients at the highest risk.^{103,105}

DURATION OF THERAPY AND ACCUMULATED DOSING

Optimum dose and duration of therapy have not been clearly defined in most fungal infections. Most of the recommended doses and guidelines presented in this chapter have been developed empirically or from extrapolation from other infections or animal models. Response and duration of treatment should be evaluated primarily on a clinical basis when feasible. Surrogate markers such as cell wall antigens or antibody assays, as well as imaging when appropriate, have also shown to be useful in infections such as cryptococcosis, histoplasmosis, and aspergillosis.

MEASUREMENT OF DRUG LEVELS

Drug level monitoring is theoretically justified to assure efficacy and avoid toxicity. However, drug level monitoring during antifungal therapy is relatively new and should not be carried out routinely because there is a lack of information on its clinical correlation and meaning. Situations in which drug level monitoring has proved to be useful are itraconazole levels to verify adequate absorption when using the oral forms of this compound, 5-FC levels to watch for possible myelotoxicity, and voriconazole/posaconazole levels to document absorption of the drugs when given orally.^{198,199}

SUSCEPTIBILITY TESTING

The Clinical Laboratory Standards Institute has published a guideline for standardized antifungal susceptibility testing that has been widely adopted²⁰⁰ and subsequently revised. This methodology is recommended for testing *Candida* and *Cryptococcus* spp. and breakpoints have been developed.²⁰¹ Antifungal susceptibility testing is now widely available and should be considered when treating serious *Candida*

infections, when treatment failure occurs, or when toxicity or side effects limit the use of a particular drug. It should also be remembered that pharmacology, safety, published experience, and drug interactions must be considered along with susceptibility when selecting a therapy.^{102,105} Mold susceptibility has also been standardized but is not routinely recommended.

ANTIVIRAL AGENTS

Antiviral chemotherapy has made great advances since the 1980s. Before then a diagnosis of a life-threatening viral infection meant mostly supportive therapy and patience. Although still limited, today we have a host of treatment options for herpetic infections; upper and lower respiratory illness by influenza, cytomegalovirus (CMV), and respiratory syncytial virus (RSV); and some relatively exotic systemic diseases. Therapy for HIV, hepatitis B, and hepatitis C infection has also made gigantic leaps, but it is usually not undertaken in the critical care setting and is thus beyond the scope of this chapter. Table 52.3 summarizes the currently available non-HIV specific antiviral drugs and their general spectrum.

ACYCLOVIR, FAMCICLOVIR, AND VALACYCLOVIR

Acyclovir is a nucleoside analog of guanine that has in vitro and in vivo activity against several viruses in the herpesvirus family, particularly against herpes simplex virus type 1 (HSV-1), HSV-2, varicella-zoster virus (VZV), and Epstein-Barr virus (EBV). High concentrations also inhibit CMV. It inhibits DNA polymerase causing DNA chain termination.²⁰²⁻²⁰⁴ Acyclovir is the treatment of choice for severe herpetic infections in immunocompetent and immunocompromised hosts. Resistance due to viral thymidine kinase mutations or, less often, DNA polymerase mutations may emerge in patients with severe immunocompromise such as transplant recipients and advanced HIV infection during treatment of HSV and VZV infections.²⁰⁵⁻²⁰⁷ Acyclovir has also been used for CMV prophylaxis in transplant patients.^{208,209} Acyclovir is available in oral, IV, and topical forms. Bioavailability of the oral form is poor (15-21%), requiring high dosage/frequent

doses. Protein binding is less than 20%. CSF penetration is low, but acyclovir is active for CNS infections. The topical form is virtually unabsorbed. The half-life is short and the drug is cleared by the kidneys, so dosage adjustment in renal failure and hemodialysis is required. Supplementation is not needed in peritoneal dialysis. Side effects are uncommon.²¹⁰ The main concern with acyclovir therapy is the crystallization of the drug in the renal tubules, leading to renal failure. Aggressive hydration and monitoring of renal function are recommended during IV acyclovir therapy. Oral acyclovir may cause nausea and vomiting. The usual oral dose is 200 to 800 mg every 4 hours. The IV dosing range for severe infections is 8 to 12 mg/kg IV every 8 hours. Proven encephalitis is treated with 10 to 12 mg/kg every 8 hours for 14 to 21 days. Doses of up to 20 mg/kg may be more effective in premature infants.²¹¹

Famciclovir, the prodrug of penciclovir (a guanosine analog),^{212,213} is a well-absorbed oral agent that has shown excellent activity against first-episode or recurrent genital herpes and HSV/VZV infection in both HIV and immunocompetent hosts.²¹⁴⁻²¹⁶ A dose of 500 mg orally three times a day was shown to be as effective as acyclovir for treatment of herpes zoster.²¹⁷

Valacyclovir, an analog of acyclovir that has a similar profile of side effects, is now available in oral formulations with the advantage of longer dosing intervals. It appears comparable to acyclovir for treatment of mucocutaneous HSV infections, but more effective in herpes zoster. It is also effective orally for prophylaxis of CMV in renal transplant patients.²¹⁸ The dosing range is 500 to 1000 mg orally two to three times a day.²¹⁹⁻²²¹ Although absorption is excellent, there is little data to support treating invasive disease, such as CNS disease, with this drug.

GANCICLOVIR AND VALGANCICLOVIR

Ganciclovir is another nucleoside analog of guanine but has a slightly wider antiviral spectrum than acyclovir. It is highly active against CMV, as well as HSV-1, HSV-2, and EBV. Like acyclovir it acts by interference with DNA polymerase, but it is not an obligate chain terminator. Resistance to ganciclovir by CMV and HSV is increasingly reported. HSV isolates that are thymidine kinase-deficient and thus resistant

Table 52.3 Spectrum of Antiviral Agents

Susceptible Virus	Acyclovir/ Valacyclovir/ Famciclovir	Ganciclovir/ Valganciclovir	Foscarnet	Cidofovir	Amantadine/ Rimantadine	Ribavirin	Oseltamivir/ Zanamivir
HSV-1	++*	++	++	++	0	0	0
HSV-2	++*	++	++	++	0	0	0
VZV	++*	++	++	++	0	0	0
CMV	±*	++*	++	++	0	0	0
EBV	+	++	++	++	0	0	0
Influenza A	0	0	0	0	++*	+	++*
Influenza B	0	0	0	0	0	+	++*

CMV, cytomegalovirus; EBV, Epstein-Barr virus; HSV, herpes simplex virus; VZV, varicella-zoster virus.

0, no known activity; ±, active under specific circumstances; +, active; ++, very active.

*Resistant strains reported.

to acyclovir will also be resistant to ganciclovir.^{207,222} It is mainly indicated in prophylaxis, treatment, and suppression of CMV syndromes in immunocompromised patients.^{208,223-227} Ganciclovir is available in oral, intraocular, and IV forms, the first two being useful only in chronic suppression of CMV disease. Once it reaches the bloodstream it has body-wide distribution, low protein binding, and low CNS penetration. Excretion is renal and dosage adjustment is required in renal failure. Ganciclovir is removed by hemodialysis, and therefore it should be administered after dialysis. Side effects of IV ganciclovir include severe neutropenia (40%), thrombocytopenia (20%), phlebitis, rash, increased liver enzymes, and azotemia. The nephrotoxicity is potentiated by concomitant use of nephrotoxic agents and acyclovir. Ganciclovir should not be used in pregnant women because it is known to be teratogenic. The usual dose in acute infection is 5 mg/kg every 12 hours. Maintenance therapy at 5 mg/kg IV every day should be continued as long as the patient is immunocompromised. Discontinuation of therapy in acquired immunodeficiency syndrome (AIDS) patients appears feasible following immune reconstitution.^{208,223,228,229} An intraocular delivery system is also available as an adjunct to the treatment of CMV retinitis.

Valganciclovir is an L-valyl ester of ganciclovir that has significantly increased bioavailability over previous oral formulations of ganciclovir, resulting in levels previously unattainable with the traditional formulations. It allows for prophylaxis and treatment of CMV infections with an oral alternative. The usual dose for prophylaxis is 900 mg orally every 24 hours, and for treatment the recommended induction dose is 900 mg orally every 12 hours, followed by a maintenance dose of 900 mg orally every 24 hours. This drug requires adjustment for patients with renal impairment.^{230,231}

CIDOFOVIR

Cidofovir is a nucleotide analog with activity against most herpesviruses. Its activation is not virus-enzyme dependent, so it has activity against most acyclovir-resistant HSV and ganciclovir-resistant CMV. Resistant strains have also been reported, and synergy with ganciclovir and foscarnet has been reported. Oral bioavailability is very low. It is 6% protein bound and is excreted by the kidneys.^{232,233} Its side effects include neutropenia and nephrotoxicity, which can manifest as proteinuria, azotemia, and a Fanconi-like renal syndrome. It has been shown to be teratogenic and mutagenic and is contraindicated in pregnancy. It is currently licensed for CMV retinitis in HIV infection but has also shown activity against acyclovir-resistant HSV.^{234,235} The usual dose is 5 mg/kg every week for 2 weeks, then 5 mg/kg every other week.

FOSCARNET

Foscarnet is a pyrophosphate analog that has antiviral activity against the herpesviruses, HIV, and hepatitis B virus. Its mechanism of action is interference with DNA polymerase or reverse transcriptase to block effective viral replication. Viral isolates that are resistant to ganciclovir or acyclovir are often susceptible to foscarnet, but primary resistance to foscarnet has also been described, particularly

in HIV-infected patients.^{205,206,236-238} The main therapeutic indication of foscarnet is ganciclovir-resistant CMV disease. Foscarnet is only available in IV formulations and it has body-wide distribution. Protein binding is 15% and it has good CSF penetration. The drug is excreted almost intact by the kidneys and requires very careful dosage adjustment in renal failure. Foscarnet is removed by hemodialysis but should be avoided in patients with severe renal dysfunction. Its main side effect is nephrotoxicity, which occurs in most patients but is reversible when therapy is stopped.²³⁹ Dosage adjustment should be made by following the CrCl closely. Hypocalcemia and hypercalcemia as well as phosphate abnormalities are common, so monitoring of electrolytes is also recommended. The usual dose is 60 mg/kg every 8 hours for CMV infections and 40 mg/kg every 8 hours for treating acyclovir-resistant HSV infections.

AMANTADINE AND RIMANTADINE

Amantadine is a tricyclic amine inhibitor of influenza A virus. Its mechanism of action involves inhibition of the transmembrane domain of the viral M2 protein, thus preventing viral uncoating during early stages of replication. It has activity against influenza A but no clinical activity against influenza B.²⁴⁰⁻²⁴³ Resistant strains can be developed in vitro and are also seen in household and nursing home contacts exposed to persons treated for acute influenza. It is indicated in influenza A prophylaxis and treatment and also for management of Parkinson's disease and drug-induced extrapyramidal reactions. It is well absorbed orally and has body-wide distribution. It is 67% bound to plasma proteins and excreted unchanged in the urine by glomerular filtration and tubular secretion. The usual adult dosage for both prophylaxis and treatment is 100 mg twice a day. The dosage must be reduced in elderly patients and patients with renal insufficiency. In individuals who are 65 or older, the dose should be reduced to 100 mg every day. The dose for a CrCl less than 10 mL/minute is 200 mg per week. The most common adverse events are related to the CNS and correlate directly with high levels. Patients may present with confusion, seizures, hallucinations, and coma. Amantadine also causes GI upset.

Rimantadine is another tricyclic amine with similar properties, spectrum, and indications as amantadine.^{244,245} The main difference lies in its extensive metabolism by the liver and its minimal renal clearance, but it also requires dosage adjustment in advanced liver and kidney insufficiency (CrCl < 10 mL/minute) as well as in the elderly. Its major advantage is less frequent CNS toxicity. Dosage is 100 mg twice a day.

RIBAVIRIN

Ribavirin is a triazole nucleoside analog that has broad-spectrum antiviral activity. It is effective in vitro against RSV, influenza A and B, HSV, HIV, hepatitis C virus, and viruses causing hemorrhagic fevers.^{215,246-248} Its currently approved clinical indications are treatment of pediatric patients with severe RSV infection, and in combination with injected interferon alfa and ribavirin capsules, it is approved for treatment of chronic hepatitis C.^{249,250} The IV form has been shown to reduce mortality rate in Korean/Asian

hemorrhagic fever with renal syndrome.²⁵¹ Its mechanism of action is not fully understood and intrinsic resistance has not been reported. It is available in oral, aerosolized, and IV formulations. It has high bioavailability through the oral or aerosolized forms and it is metabolized by the liver. Toxicity in the aerosolized formulation consists primarily of severe bronchospasm and cardiac rhythm abnormalities. The IV formulation also causes hemolytic anemia. Use in ventilated patients requires experienced personnel because environmental leaking and diffusion are common.²⁵² Recommended dosage is 1.1 g/day of ribavirin administered by continuous aerosolization for 12 to 18 hours/day for 3 to 7 days. It should not be combined with other aerosolized medications. Induction of bronchospasm is common, and scheduled use of a bronchodilator may be required during ribavirin therapy.

OSELTAMIVIR

Oseltamivir is a sialic acid neuraminidase inhibitor that has recently become available for the treatment of both influenza A and B.²⁵³⁻²⁵⁵ Its mechanism of action is inhibition of the viral neuraminidase, causing in turn inhibition of virus release from infected cells and spread in the respiratory tract. Drug resistance has already been reported in vitro in strains with mutations that cause changes in the viral neuraminidase or hemagglutinin. In clinical studies of adults, only 1% to 2% of posttreatment strains showed evidence of mutations with decreased neuraminidase susceptibility. Recent reports have mentioned infrequent resistance in avian influenza and H1N1 strains.²⁵⁶⁻²⁵⁸ Cross-resistance between oseltamivir and zanamivir, the other member of the class, has also been observed in vitro. It is indicated for the prevention and early treatment of uncomplicated acute influenza A and B.²⁵⁹ Major clinical trials have demonstrated that oseltamivir reduces the duration, severity, and rate of complications requiring antibiotic use.²⁵⁵ Its role in complicated cases such as those seen in the critical care setting is unclear at this time, although the 2009 H1N1 epidemic contributed a wealth of data related to its use in critically ill patients.^{260,261} Oseltamivir is available in an oral form, which has greater than 75% bioavailability. The drug is converted to oseltamivir carboxylate that is eliminated unchanged in the urine. Less than 20% of the dose is eliminated in feces. Dose adjustment is recommended for renal failure and geriatric patients when CrCl is less than 30 mL/minute.²⁶² The recommended dose in such settings is 75 mg orally every 24 hours for 5 days. Clinically relevant drug interactions have not been identified. Side effects, which include nausea, vomiting, and abdominal pain, are usually mild. The recommended dosage is 75 mg orally twice daily for 5 days and it is recommended that treatment is begun within 2 days of symptom onset. New formulations of IV oseltamivir are being developed.²⁶³

ZANAMIVIR

Zanamivir is another sialic acid analog neuraminidase inhibitor that was recently approved for the treatment of both influenza A and B.^{253,264} Much like oseltamivir, its mechanism of action is by neuraminidase inhibition with subsequent inhibition of viral release and spread. Resistant strains

have also been identified in vitro, and a resistant strain was also recovered from an immunocompromised patient with influenza B after 2 weeks of nebulized treatment.^{265,266} It is indicated in acute cases of influenza with early onset of treatment.^{254,267-269} Trials on patients with more severe disease are ongoing.^{270,271} Experience is also building with its use in prophylaxis.^{240,272,273} Zanamivir is available in a powder form for oral inhalation. A new IV formulation is also under development.²⁷⁴ Approximately 4% to 17% of the dose is absorbed and less than 10% of the drug is protein bound. It is excreted unchanged in the urine and unabsorbed drug is cleared in the feces. No dosage adjustment in renal or hepatic failure is recommended at this time, but experience is limited. Zanamivir does not have significant drug interactions.^{275,276} Bronchospasm may be precipitated particularly in patients with underlying lung disease.²⁷⁷ The recommended dose is 10 mg (two inhalations) twice a day for 5 days.

SPECIFIC INDICATIONS AND USES FOR ANTIVIRAL THERAPY

HERPES SIMPLEX AND VARICELLA-ZOSTER

Acyclovir, famciclovir, and valacyclovir are the drugs of choice in the treatment of virtually all severe herpetic infections.^{203,204, 215, 278-285} The greater oral bioavailability of famciclovir and valacyclovir makes these agents very attractive, especially for treatment of VZV. Although primary HSV-1 and -2 infections can be treated orally, immunocompromised patients or severely ill patients will require IV therapy. A high index of suspicion for dissemination should be maintained in immunocompromised patients—mild, localized, or atypical disease may progress to fulminant disease. Duration of therapy in this setting is usually 7 to 14 days.

Herpetic encephalitis has had a substantial decrease in morbidity and mortality rates since acyclovir was introduced. Being one of the few forms of viral encephalitis for which there is a treatment, empirical use of the drug is justified when viral disease is suspected and until it is ruled out. HSV polymerase chain reaction (PCR) of CSF is a very sensitive and specific test for the diagnosis of this disease. The usual dose is 10 to 12 mg/kg every 8 hours for 14 to 21 days. Visceral infections, including esophagitis, hepatitis, pneumonia, and disseminated disease, are frequent in immunocompromised patients and should be treated with 5 to 10 mg/kg every 8 hours for 14 to 21 days. HSV may also cause aseptic meningitis without encephalitis in setting of primary or recurrent genital HSV infection. Unlike the focal necrotizing disease seen with HSV encephalitis, this form of the disease is a mild self-limited aseptic meningitis with a good prognosis.

Finally, acyclovir-resistant HSV infections, which are an increasing problem in the immunocompromised population,^{206,207, 286,287} can be treated with foscarnet or cidofovir.

Primary VZV infection (chickenpox) should be treated in all adults, especially in the immunocompromised.^{278,281,285,288,289} Reactivation (shingles) should be treated because treatment has been shown to decrease duration and intensity of symptoms.^{290,291} Mild cases may be treated

with oral famciclovir or valacyclovir. Severe cases (disseminated, immunocompromised patients with involvement of more than one dermatome, or ophthalmic involvement) should be treated with IV acyclovir. It is important to remember that these patients are contagious and should be suitably isolated using airborne precautions. As with HSV, resistant strains may be treated with foscarnet.^{292,293}

CYTOMEGALOVIRUS INFECTION

CMV infections require treatment in immunocompromised patients. Populations at increased risk of the disease are HIV-infected patients and transplant recipients. In HIV patients, both retinal and visceral involvement are initially treated with IV ganciclovir at 5 mg/kg every 12 hours for 2 weeks.^{208,223,224} Valganciclovir is a suitable oral formulation for the treatment of this infection. Various maintenance options are increasingly available (including ganciclovir ocular implants) but are beyond the scope of this chapter. Resistant cases may be treated with foscarnet 60 mg/kg every 8 hours for 2 weeks^{229,236} or cidofovir. Clinical and laboratory monitoring while on either of these drugs is essential to avoid therapy-related complications. Refractory cases may be treated with cidofovir.

In the transplant patient, the combination of ganciclovir and IV immunoglobulin is now the treatment of choice for CMV pneumonia.^{223,294-296} High doses of acyclovir are useful as prophylaxis of CMV in the transplant patient but not in the HIV setting. Ganciclovir-resistant strains should be treated with foscarnet.

INFLUENZA

Clear benefit in the treatment of influenza is consistently seen only when patients are treated early in the course of the disease.^{253,297-300} Therapeutic options (which can also be used prophylactically) include amantadine/rimantadine, oseltamivir, and zanamivir.³⁰¹⁻³⁰⁶ In patients who present later in the course of the disease, the benefits of therapy are unstudied. Prevention of complications has not been clearly demonstrated. Further trials are required to demonstrate whether one class of drugs is superior to the other and whether they have a role in the critically ill patient. Rapid diagnosis of influenza is now available through different techniques that detect viral components in upper respiratory tract samples. These techniques are useful in detecting and treating infected hospitalized patients early and in regional surveillance of influenza. However, a negative test does not completely rule out influenza, and empirical therapy of ambulatory patients with a clinical syndrome strongly suggesting influenza is probably appropriate.

Avian and pandemic influenza have received much attention from the scientific community and the media in the past 2 years. Considerable efforts are being carried out for surveillance, prompt detection, and containment of these diseases.³⁰⁷⁻³¹⁰ Critical care specialists should have increased awareness and involve infection control and public health authorities in patients with particularly severe forms of influenza with the appropriate epidemiologic background. Suspected and confirmed cases should be placed on airborne precautions. As mentioned earlier, although there are scarce reports of neuraminidase inhibitor resistance in some avian

influenza strains, these viruses appear to be generally susceptible to oseltamivir and zanamivir.^{256,257}

The 2009 H1N1 epidemic virtually changed how we manage influenza in critically ill patients. During this epidemic oseltamivir and zanamivir were frequently used late in the disease and at high doses, also in the setting of extracorporeal membrane oxygenation (ECMO), with variable results.^{261, 270, 311-313} At this point the true value of these agents is still unknown, although most experts agree that at the very least they may decrease viral shedding and transmission.

An important consideration is vaccination and postexposure prophylaxis in health care personnel working in acute and chronic care facilities. Appropriate vaccination and influenza control measures in both health care personnel and patients has proved to be effective in decreasing disease and even mortality rates in patients.³¹⁴⁻³¹⁶

OTHER VIRAL INFECTIONS

Other potentially treatable viral infections that may be encountered in the critical care setting include parvovirus, for which treatment with IV immunoglobulin has shown some beneficial effects;³¹⁷⁻³¹⁹ enterovirus, for which a new drug called pleconaril showed only marginal benefits in the setting of meningitis;^{320,321} and hemorrhagic fevers and hantavirus, for which ribavirin may be considered despite lack of definitive proof of efficacy.²⁴⁸ Dengue and yellow fever can be particularly severe and are most effectively managed with aggressive supportive care.

KEY POINTS

- Amphotericin B and its lipid preparations are the treatment of choice for all critically ill patients with an undiagnosed fungal infection. Once diagnosis is made, other therapeutic options may be considered.
- Fluconazole has excellent antifungal activity, mainly against yeasts, but resistance is possible and clinically relevant.
- The echinocandins are a class of antifungal agents with activity against *Candida* and *Aspergillus* with proven efficacy and remarkable safety profiles. They are now considered the treatment of choice for candidemia in critically ill patients.
- Combinations of antifungal agents should be approached carefully, being clearly beneficial only in selected entities such as CNS disease and endocarditis.
- Empirical antifungal use and antifungal prophylaxis in the ICU setting remain controversial and should be reserved for carefully selected units and patients.
- Uncommon and serious mycoses require expert consultation.
- Acyclovir and its analogs are the drugs of choice for treatment of HSV and VZV infections. The new oral formulations (famciclovir and valacyclovir) have

Continued on following page

KEY POINTS (Continued)

- greater bioavailability and are preferred in ambulatory patients.
- Ganciclovir is the drug of choice for treatment of CMV infection in immunocompromised hosts. Immunoglobulin therapy is added to this in transplant patients with pneumonia.
- Critical care specialists should have a high index of suspicion for avian and pandemic influenza. Suspected or confirmed cases should be placed on airborne precautions and treated with neuraminidase inhibitors.
- Resistance is an increasing problem in both antifungal and antiviral therapy.

Critically Ill Immunosuppressed Host

Henry Masur

CHAPTER OUTLINE

DEFINITION

HOST DEFENSE MECHANISMS

GENERAL APPROACH TO MANAGEMENT

MANAGEMENT OF SPECIFIC PATIENT

POPULATIONS

Cancer Patients with Neutropenia

Patients with HIV/AIDS

Human Stem Cell, Bone Marrow, and Solid

Organ Transplant Recipients

Patients often become immunosuppressed due to congenital or acquired disease. Additional patients become immunosuppressed because of the therapies that are being used to manage an expanding number of serious underlying conditions. Immunosuppressed patients present special management issues because (1) opportunistic infections often require special diagnostic tests; (2) opportunistic infections can be fulminant but can present without the usual expected signs and symptoms; and (3) patients are often receiving multiple unfamiliar drugs, which can have complex interactions that can lead to reduced drug efficacy or increased toxicity for the drugs related to the immunosuppressive illness or for drugs used for the management of critical care complications.

This chapter emphasizes the important ways in which immunosuppressed patients differ from immunologically normal individuals in terms of infectious complications. The noninfectious complications of immunosuppression are reviewed in Chapter 80.

DEFINITION

Patients who are at increased risk for infectious complications because of a deficiency in any of their host defense mechanisms are referred to as *compromised* hosts. Almost all patients in the intensive care unit (ICU) are compromised because devices, such as intravascular catheters, compromise their physical barriers of defense. Patients are termed *immunocompromised* or *immunosuppressed* if their defect specifically involves immune response (i.e., their innate immunity or their acquired immunity). Patients who have defects in inflammatory response, such as neutropenia or congenital leukocyte abnormalities, are also considered immunosuppressed in most reviews.

HOST DEFENSE MECHANISMS

The microbial complications that any patient develops in the ICU are determined by general, nonspecific barriers; innate immunity; acquired specific immunity; and environmental exposures. Nonspecific barriers include anatomic barriers such as intact skin and mucous membranes; chemical barriers, such as gastric acidity or urine pH; and flushing mechanisms, such as urinary flow or mucociliary transport in the lungs. Organisms that breach these barriers encounter nonspecific and innate host factors termed the *acute phase response*. Acute phase responses trigger a cascade of acquired specific immune responses including mononuclear phagocytes and antibodies, which also trigger a cascade of effector molecules and nonspecific inflammatory responses.¹

Infections result from normal flora that colonize mucosal or cutaneous surfaces or from abnormal flora that are introduced by surface-to-surface contact, inhalation, ingestion, trauma, or medical procedures. [Table 53.1](#) lists organisms that cause disease when specific anatomic defenses are disrupted in individuals with normal microbial flora. Patients with abnormal flora will develop disease that reflects unique, disease-specific characteristics of the host, the abnormal environment, and modifying factors such as drugs. Infections that result from common defects in the inflammatory or immunologic systems are detailed in [Table 53.2](#).

Immunosuppressed patients are complicated because they generally have multiple factors that change the causes and manifestations of their infectious complications. Patients with hematologic malignancies, for instance, may be predisposed to infection because their leukemia or lymphoma has eliminated functional cells from their bone marrow. In addition, however, ablative chemotherapy may

Table 53.1 Normal Flora That Can Cause Disease When Anatomic Barriers Are Disrupted

Compromised Host Defense: Anatomic Disruption	Bacteria	Fungi
Oral cavity, esophagus	α -Hemolytic streptococci, oral anaerobes	<i>Candida</i> species
Lower gastrointestinal tract	Enterococci Enteric organisms Anaerobes	<i>Candida</i> species
Skin	Gram-positive bacilli Staphylococci, streptococci <i>Corynebacterium</i> , <i>Bacillus</i> species <i>Mycobacterium fortuitum</i> , <i>Mycobacterium chelonae</i>	<i>Candida</i> species <i>Aspergillus</i>
Urinary tract	Enterococci Enteric organisms	<i>Candida</i> species

Table 53.2 Infections Associated with Common Defects in Inflammatory or Immunologic Response

Host Defect	Examples of Associated Diseases/Therapies	Common Etiologic Agents of Infection
Inflammatory Response		
Neutropenia	Hematologic malignancies, cytotoxic chemotherapy, aplastic anemia	Gram-negative bacilli, <i>Staphylococcus aureus</i> , <i>Candida</i> species, <i>Aspergillus</i> species
Complement System		
C3	Congenital liver disease Systemic lupus erythematosus	<i>S. aureus</i> , <i>Staphylococcus pneumoniae</i> , <i>Pseudomonas</i> species, <i>Proteus</i> species
Alternate pathway	Sickle cell disease	<i>S. pneumoniae</i> , <i>Salmonella</i>
Immune Response		
T lymphocyte deficiency/ dysfunction	Thymic aplasia, thymic hypoplasia, Hodgkin disease, sarcoid Human immunodeficiency virus infection	<i>Listeria monocytogenes</i> , <i>Mycobacterium</i> species, <i>Candida</i> species, <i>Aspergillus</i> species, <i>Cryptococcus neoformans</i> , herpes simplex, herpes zoster <i>Pneumocystis jiroveci</i> , cytomegalovirus, herpes simplex virus, <i>Mycobacterium avium</i> complex, <i>C. neoformans</i> , <i>Candida</i> species
B-cell deficiency/ dysfunction	Mucocutaneous candidiasis Splenectomy, chronic lymphocytic leukemia, hypogammaglobulinemia, chronic lymphocytic leukemia, multiple myeloma, dysgammaglobulinemia Selective IgA deficiency	<i>Candida</i> species <i>S. pneumoniae</i> , other streptococci, <i>Haemophilus influenzae</i> , <i>Neisseria meningitidis</i> , <i>Babesia</i> species, <i>Capnocytophaga</i> , <i>Giardia lamblia</i> , <i>P. jiroveci</i> , enteroviruses <i>G. lamblia</i> , viral hepatitis, <i>S. pneumoniae</i> , <i>H. influenzae</i>
Mixed T- and B-cell deficiency/dysfunction	Common variable hypogammaglobulinemia	<i>P. jiroveci</i> , cytomegalovirus, <i>S. pneumoniae</i> , <i>H. influenzae</i> , varicella virus, other bacteria

IgA, immunoglobulin A.

have eroded their mucosal surfaces and may have also altered their cellular immune responses or their neutrophil function.

Because of these host defense defects, organisms may cause local tissue destruction due to primary infection or reactivation and may gain access to the capillaries and lymphatics with unusual facility. Microbes that usually do not cause disease, such as BK virus, *Cytomegalovirus* (CMV), *Aspergillus*, and *Mucor*, can cause devastating organ damage or systemic inflammatory syndromes.

Recognition of which host defense mechanisms are disrupted enables the clinician to focus diagnostic,

therapeutic, and prophylactic management and optimize patient outcome. For instance, if a patient presents with severe hypoxemia and diffuse pulmonary infiltrates, a health care provider who recognizes a prior splenectomy as the major predisposition to infection would focus the diagnostic evaluation and the empiric therapy on *Streptococcus pneumoniae* and *Haemophilus influenzae*.^{2,3} By contrast, if the patient's major predisposition to infection was human immunodeficiency virus (HIV) infection with a CD4⁺ T lymphocyte count below 50 cells/ μ L, the health care provider would focus on *Pneumocystis jiroveci* and *S. pneumoniae*.^{4,5} However, additional history is also necessary: if the

Table 53.3 Modification of Standard Empiric Therapy in Patients with Neutropenia

Clinical Event	Possible Modifications of Standard Empiric Therapy
Breakthrough bacteremia	For gram-positive isolate (e.g., <i>Staphylococcus aureus</i>): Add vancomycin or daptomycin or linezolid until susceptibility pattern of isolate is known. For gram-negative isolate: Add two new agents likely to have activity until susceptibility pattern of pathogen is known.
Cellulitis or catheter-associated infection	Add vancomycin or daptomycin.
Severe necrotizing mucositis or gingivitis	Add specific antianaerobic agent (e.g., metronidazole, meropenem, imipenem, piperacillin-tazobactam) plus agent with activity against streptococci; consider acyclovir.
Ulcerative mucositis or gingivitis	Add acyclovir and anaerobic coverage.
Esophagitis	Add fluconazole or caspofungin; consider adding acyclovir.
Pneumonitis, diffuse or interstitial	Add trimethoprim-sulfamethoxazole and azithromycin or levofloxacin or moxifloxacin (plus broad-spectrum antibiotics if the patient is granulocytopenic).
Perianal tenderness	Include anaerobic agents such as metronidazole, imipenem, meropenem, or piperacillin-tazobactam.
Abdominal involvement	Add antianaerobic agent (e.g., metronidazole, meropenem, imipenem, piperacillin-tazobactam).

Figure 53.1 Incidence of infection in acute leukemia patients during induction therapy. (From Bodey GP, Buckley M, Sathe YS, Freireich EJ: Quantitative relationships between circulating leukocytes and infection in patients with acute leukemia. *Ann Intern Med* 1966;64(2):328-340.)

pneumonia occurs during an influenza outbreak, after exposure to a water aerosol (*Legionella*), or after a seizure (aspiration), the likely cause is plausibly linked to the precipitating event.

Immune competence should ideally be measurable by objective laboratory parameters. In fact, the risk for opportunistic infection in patients with HIV infection can be assessed by clinical laboratories with a high degree of accuracy by measuring the number of circulating CD4⁺ T lymphocytes. The susceptibility of cancer patients to opportunistic bacterial and *Candida* infections can be assessed by measuring the number of circulating neutrophils (Fig. 53.1), and treatment algorithms have been established

for managing fever in such patients (Figs. 53.2 to 53.4) and Table 53.3).⁶ The predisposition of patients with certain congenital immunodeficiencies can be assessed by measuring serum immunoglobulin levels.⁷ Unfortunately, however, for a large number of immunodeficiencies, such as those associated with antilymphocyte monoclonal antibodies or corticosteroids, no objective laboratory measures have been validated as predicting the risk of infection. Moreover, each parameter must be validated for each specific disease entity: for instance, although CD4⁺ T-cell counts are excellent predictors of opportunistic infection predisposition for patients with HIV/AIDS (acquired immunodeficiency syndrome) (Fig. 53.5), they are not clinically useful for other immunosuppressive disorders.

Clinical series that document the frequency, the timing, and the causative organisms associated with infectious complications are extremely valuable for managing specific populations of immunosuppressed patients. Timelines that depict the time periods of vulnerability following stem cell transplantation (Figs. 53.6 and 53.7) and solid organ transplants (Fig. 53.8) are very useful for clinicians in terms of guiding diagnostic evaluations and for guiding empiric therapy. However, a specific microbial diagnosis should be established for each syndrome that presents in an immunosuppressed patient because the range of possible pathogens is quite broad, and the timelines and laboratory parameters cannot take into account all of the individual patient variables that influence the infectious complications that develop. Although it is useful to narrow the list of likely pathogens by analyzing risk factors, identifying the true causative agents allows therapy to be focused, avoiding unnecessary toxicity and allowing specific therapy to be optimized for efficacy and safety.

GENERAL APPROACH TO MANAGEMENT

With regard to infectious complications, effective management of immunosuppressed patients requires an understanding of several basic tenets of care.

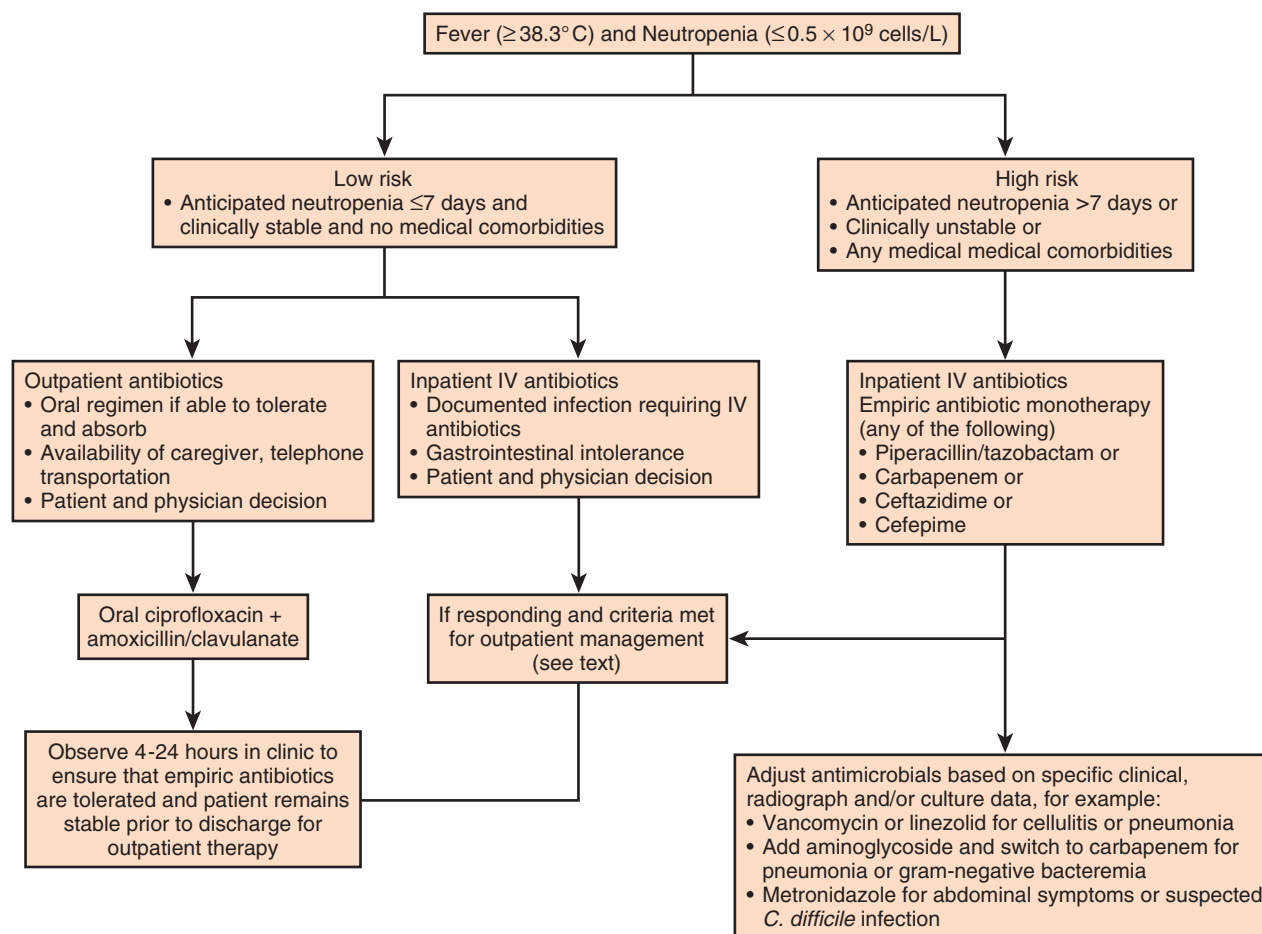

Figure 53.2 Initial management of fever and neutropenia. (From Freifeld AG, Bow EJ, Sepkowitz KA, et al: Clinical practice guideline for the use of antimicrobial agents in neutropenic patients with cancer: 2010 update by the Infectious Diseases Society of America. Clin Infect Dis 2011;52(4):e56-e93, used by permission of Oxford University Press.)

1. Life-threatening complications often present with subtle symptoms and signs that can easily be overlooked.

Because immunocompromised patients may lack inflammatory and immunologic mediators, the clinical manifestations of infections are often less prominent and less impressive than in immunocompetent patients with similar complications. Thus, clinicians must recognize that even subtle changes in temperature, skin color, tenderness, catheter site appearance, chest radiograph, or abdominal examination may warrant an aggressive diagnostic evaluation and early institution of broad-spectrum empiric therapy.

2. Fever is not invariably present when patients are infected.

Fever and infection are often seen as equivalent. However, most clinicians recognize that in any patient population there are many noninfectious causes of fever. Conversely, many patients with infection do not have fever: some infected patients may in fact be hypothermic. Corticosteroids and blunted neutropenia are often implicated in the suppression of fever. When dealing with immunosuppressed patients, clinicians need to keep these concepts in mind so that patients do not get unnecessary antibiotics when there is a likely noninfectious cause of the fever. Similarly, afebrile

patients with syndromes that could be infectious need consideration for prompt antimicrobial therapy even if there is no measurable temperature elevation.

For immunosuppressed patients, it is invariably preferable to assume that fever is due to infection and to treat empirically until the situation is fully evaluated. Although many cases of fever and neutropenia may well be noninfectious, the consequences of late treatment are so dire that prompt and broad-spectrum initiation of antimicrobial therapy should almost always be the default management approach.

3. Patients are predisposed to deteriorate precipitously.

Although all ICU patients demand prompt attention and vigorous diagnostic and therapeutic management, many types of immunosuppression can be associated with especially precipitous clinical deterioration despite their innocuous presentation. Thus, infected patients who are neutropenic or who have undergone splenectomy, for example, are especially likely to have a fulminant course.

4. Diagnostic evaluation needs to be prompt and definitive.

As indicated earlier, patients with life-threatening infection may present with subtle symptoms and signs that progress rapidly to become florid: these early

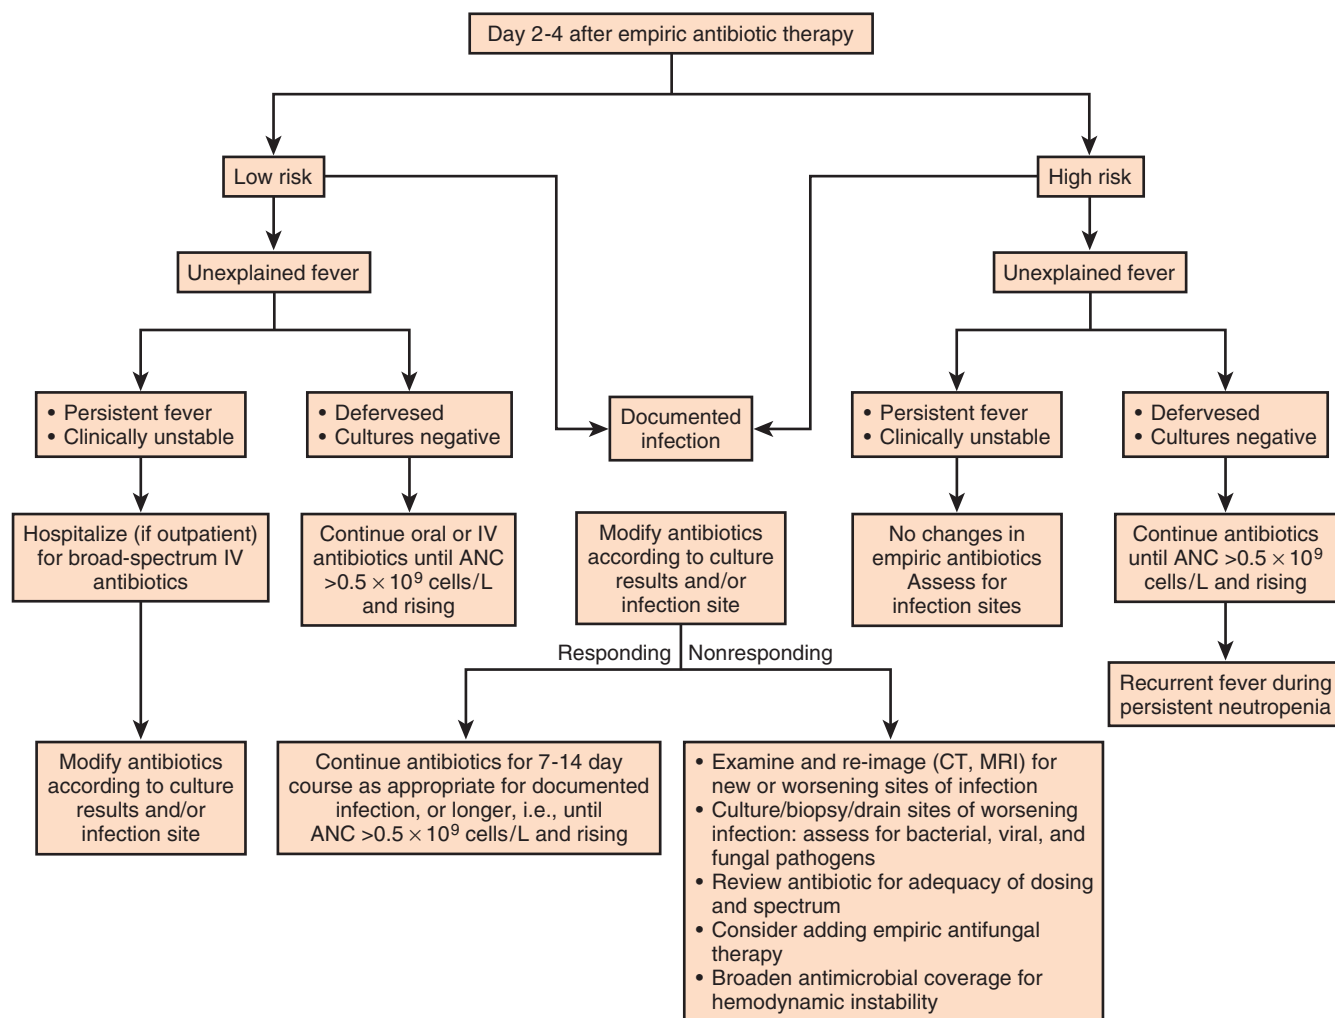

Figure 53.3 Reassessment after 2 to 4 days of empiric antibiotic therapy. ANC, absolute neutrophil count; CT, computed tomography; IV, intravenous; MRI, magnetic resonance imaging. (From Freifeld AG, Bow EJ, Sepkowitz KA, et al: Clinical practice guideline for the use of antimicrobial agents in neutropenic patients with cancer: 2010 update by the Infectious Diseases Society of America. *Clin Infect Dis* 2011;52(4):e56-e93, used by permission of Oxford University Press.)

manifestations merit aggressive attempts to define the anatomy of the lesion and the causative microbial pathogen. Because the spectrum of potential pathogens in such patients usually includes a wide array of microorganisms (e.g., viruses, fungi, protozoa, and bacteria), clinicians must be certain that appropriate specimens are obtained and the appropriate microbiologic and histologic tests are ordered to identify common, as well as uncommon or unusual, pathogens. This choice requires knowledge of the patient's underlying immunosuppressive disorder. Invasive diagnostic techniques such as bronchoalveolar lavage or tissue biopsies should be performed with less hesitancy than in immunologically normal patients. Patients often have enhanced risk factors for invasive procedures, such as thrombocytopenia, coagulation factor deficiencies, or compromised organ function. However, the benefit of definitive diagnosis often outweighs these risks when the procedures are performed by experienced operators. It is also important to recognize that timing is important: delay in scheduling diagnostic procedures may result in the patient being too hypoxic for bronchoscopy, too

unstable for computed tomography (CT) scan or magnetic resonance imaging (MRI), or too coagulopathic for a lumbar puncture or needle aspirate of a fluid collection.

5. Infections may be community acquired, nosocomial, or latent, emphasizing the need for a thorough history of the patient's prior infections and exposures in order to assure the proper diagnostic tests and the optimal empiric therapeutic regimens.
6. Not all infections are related to the underlying disease or immunosuppression.

Immunosuppressed patients may be admitted to the ICU with an infection related to their immunosuppression. However, they may also develop infections that occur in normal hosts. Thus, aspiration pneumonia, catheter-related infections, influenza, mycoplasma infection, syphilis, or malaria may occur in relation to activities of daily living, substance abuse, travel, or community exposures.

7. Empiric therapy should be started promptly.

Time to appropriate antibiotics is an important correlate of successful outcome in any patient outcome,

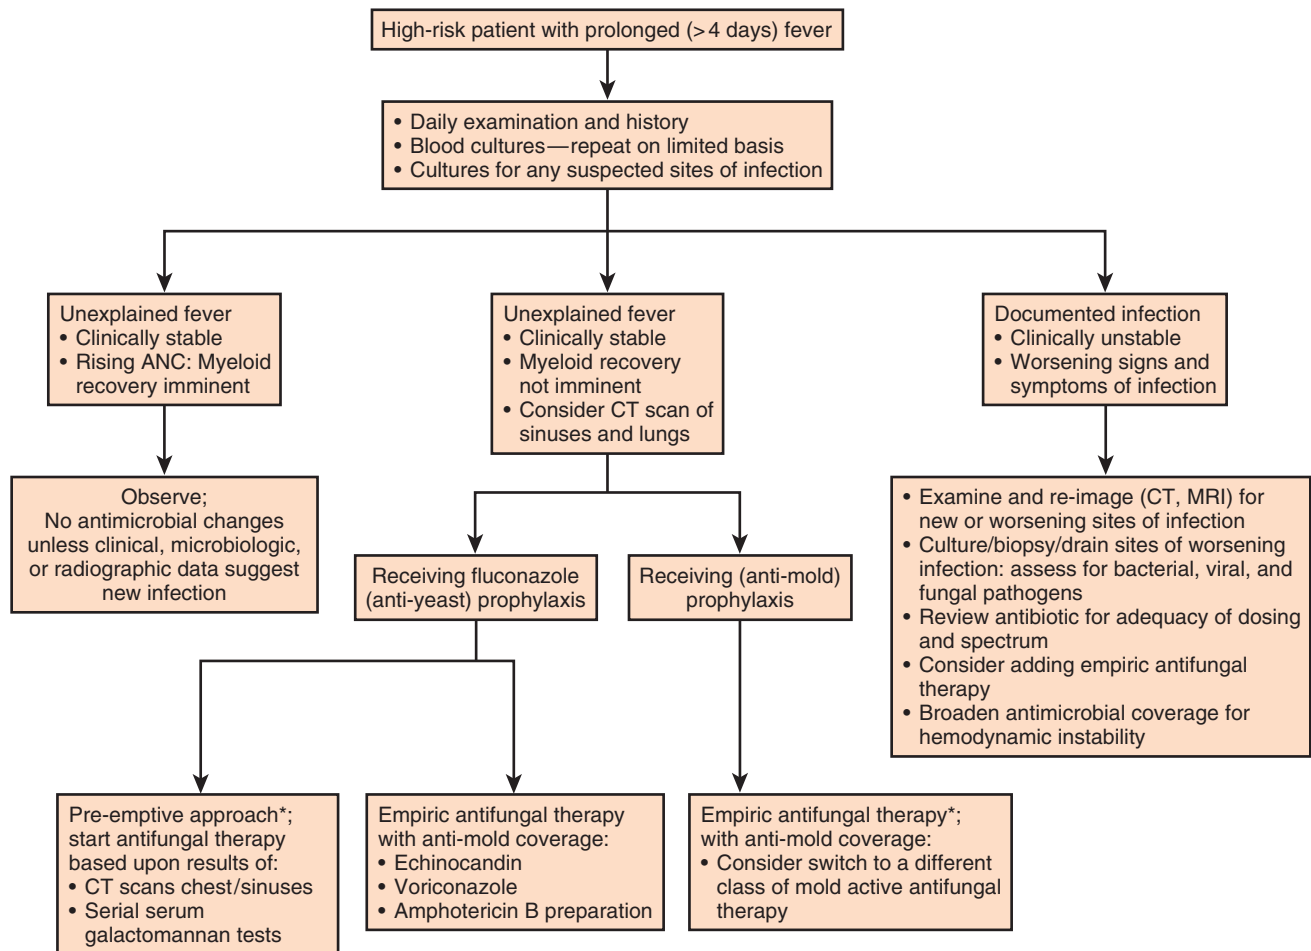

Figure 53.4 High-risk patient with fever after 4 days of empiric antibiotics. *C. difficile*, *Clostridium difficile*; IV, intravenous. (From Freifeld AG, Bow EJ, Sepkowitz KA, et al: Clinical practice guideline for the use of antimicrobial agents in neutropenic patients with cancer: 2010 update by the Infectious Diseases Society of America, Clin Infect Dis 2011;52(4):e56-e93, used by permission of Oxford University Press.)

DISTRIBUTION OF CD4⁺ T LYMPHOCYTE COUNTS AT DIAGNOSIS OF OPPORTUNISTIC INFECTION
1990-1994

Figure 53.5 CD4⁺ cell count range for common manifestations of acquired immunodeficiency syndrome. Cand Esoph, *Candida* esophagitis; cervical CA, cervical cancer; CMV Other, other cytomegalovirus diseases; CMV Ret, cytomegalovirus retinitis; Crypt, cryptococcosis; Cocci, coccidioidomycosis; Crypt, cryptosporidiosis; dTB, disseminated tuberculosis; HISTO, histoplasmosis; HSV, herpes simplex virus; MAC, *Mycobacterium avium* complex; PCP, *Pneumocystis jiroveci* pneumonia; pTB, pulmonary tuberculosis; Strep Pneumo, *Streptococcus pneumoniae*; TOXO, toxoplasmosis.

Figure 53.6 Approximate immune cell counts (expressed as percentage of normal counts) peri- and post-MA HCT. Nadirs are higher and occur later after NMA than MA transplantation, as recipient cells persist after NMA transplant for several weeks to months (in the presence of GVHD) or longer (in the absence of GVHD). The orange line represents the innate immune cells (e.g., neutrophils, monocytes, and NK cells), the recovery of which is influenced by the graft type (fastest with filgrastim-mobilized blood stem cells, intermediate with marrow, and slowest with UCB). The green line represents the recovery of CD8⁺ T cells and B cells, the counts of which may transiently become supranormal. B cell recovery is influenced by graft type (fastest after CB transplant), and is delayed by GVHD and its treatment. The blue line represents the recovery of relatively radiotherapy/chemotherapy-resistant cells such as plasma cells, tissue dendritic cells (e.g., Langerhans cells) and, perhaps, tissue macrophages/microglia. The nadir of these cells may be lower in patients with aGVHD because of graft-versus-host plasma cell/Langerhans cell effect. The red line represents CD4⁺ T cells, the recovery of which is influenced primarily by T cell content of the graft and patient age (faster in children than adults). aGVHD, acute graft-versus-host disease; GVHD, graft-versus-host disease; HCT, hematopoietic cell transplantation; MA, myeloablative; NK, natural killer; NMA, nonmyeloablative; UCB, umbilical cord blood. (From Storek J: Immunological reconstitution after hematopoietic cell transplantation—its relation to the contents of the graft. *Expert Opin Biol Ther* (Informa) 2008;8:583-597. Reproduced with permission of Informa Healthcare [Storek J: Immunological reconstitution after hematopoietic cell transplantation—its relation to the contents of the graft. *Expert Opin Biol Ther* (Informa) 2008;8:583-597], and Elsevier [Tomblin M, Chiller T, Einsele H, et al: Guidelines for preventing infectious complications among hematopoietic cell transplantation recipients: A global perspective. *Biol Blood Marrow Transplant* 2009;15:1143-1238.]

but time is especially important in these patients, who are prone to deteriorate rapidly. Thus, the clinician must assure that the drugs are received by the patient and that there are no delaying factors related to pharmacy preparation, team communication, vascular access, or other factors.

Intensivists are more and more aware of the importance for all patients of “time to antibiotics,” that is, the importance of starting antibiotics sooner rather than later, and including a drug that is active against the

pathogen that is ultimately shown to be the causative organism.^{8,9}

8. Empiric therapy should be broad spectrum.

Antimicrobial stewardship is an important principle for preserving antibiotic efficacy on a population basis and for reducing unnecessary drug toxicities. However, given the breadth of pathogens that can cause the disease, and the often precipitous and sometimes irreversible clinical decline in this patient population, empiric regimens should be rational but very broad spectrum, with rapid narrowing of the regimen as further diagnostic information becomes available.

9. Antibiotic therapy should be narrowed when the causative organism is known, and monotherapy is usually adequate.

The development of potent β -lactam and quinolone drugs in the 1980s and 1990s provided single agents that appear to be as effective as combination therapy for the treatment of gram-negative bacillary infections.¹⁰⁻¹⁵

For aerobic gram-positive cocci, drugs such as oxacillin, vancomycin, and daptomycin appear to be as active as any combination regimen, except for endocarditis and infections involving prosthetic devices. Similarly, for most fungal and viral diseases, no combination therapy is documented to be more potent than the appropriate single-drug therapy.

Exceptions may occur when pathogens are not highly susceptible to any available agent. However, both the microbial environment and the patient usually benefit from narrowing of the antibiotic regimen so that unnecessary toxicity and unneeded microbial resistance are not facilitated.

10. Foreign bodies and infectious foci should be assessed promptly for drainage or removal.

When immunosuppressed patients are infected or septic, prompt consideration should be given to replacing all intravascular catheters and to assessing the patient for drainable foci of infection. Antimicrobial therapy may not be effective until such foci are drained or removed. Because some intravascular lines are not easy to replace or drainage procedures in some complicated patients may entail considerable potential morbidity, such decisions require considerable judgment.

11. Consideration should be given to reducing the level of immunosuppression.

There is no proven survival benefit to interventions meant to augment or improve the immune or inflammatory response such as granulocyte colony-stimulating factor, neutrophil transfusions, or cytokines. It is plausible to reduce immunosuppression by reducing the dose of corticosteroid or other immunosuppressive agent if that is clinically feasible. Some institutions administer granulocyte infusions or colony-stimulating factors for patients with established infections. There is no documentation that such interventions improve survival, and deleterious effects, especially from granulocyte transfusions, can be life-threatening.^{16,17}

12. The effectiveness and safety of antimicrobial therapy should be monitored regularly.

ICU patients characteristically require attentive monitoring to assure the adequacy and safety of therapy. Immunocompromised patients often have multiple

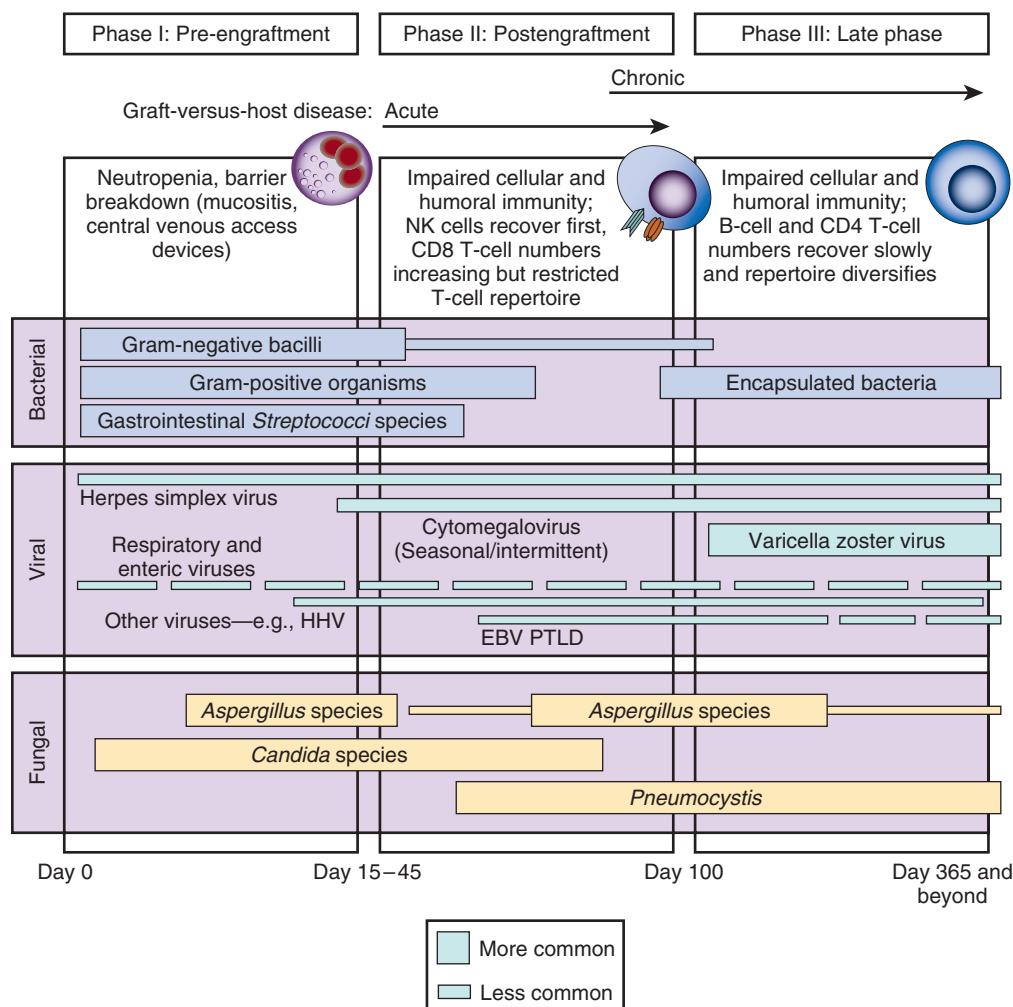

Figure 53.7 Phases of opportunistic infections among allogeneic HCT recipients. EBV, Epstein-Barr virus; HCT, hematopoietic cell transplantation; HHV6, human herpes virus 6; PTLD, posttransplant lymphoproliferative disease. (From Tomblyn M, Chiller T, Einsele H, et al: Guidelines for preventing infectious complications among hematopoietic cell transplantation recipients: A global perspective. *Biol Blood Marrow Transplant* 2009;15:1143-1238.)

prior and concurrent insults to their renal and hepatic function, and they often receive multiple drugs that can produce drug-drug interactions. Further, their volume of distributions may change dramatically from day to day. Thus, monitoring the pharmacokinetics and assessing potential toxicities are especially important in these patient populations. Moreover, because response to therapy may be less robust than in immunocompetent patients, serial antigen titers or polymerase chain reaction (PCR) titers, as well as serial imaging studies, can be important to assure the adequacy of the management plan. Therapy must often be continued longer than in immunologically normal patients while awaiting return of immunologic or inflammatory host response, or awaiting a sluggish therapeutic response in the face of ongoing immunosuppression.

13. Noninfectious syndromes can masquerade as infections and can be life-threatening.

Clinicians dealing with specific populations must be familiar with the noninfectious syndromes that occur, such as graft-versus-host disease, immune reconstitution syndrome, bronchiolitis obliterans, cardiomyopathy/

pulmonary edema, and veno-occlusive disease of the liver. Failure to recognize these entities deprives patients of appropriate therapy, and exposes them to the toxicities and expense of unnecessary antimicrobial therapy.

MANAGEMENT OF SPECIFIC PATIENT POPULATIONS

CANCER PATIENTS WITH NEUTROPENIA

GENERAL PRINCIPLES

Cytotoxic therapy-induced neutropenia is a major predisposition to infection.⁶ Neutrophil counts below 1000 cells/ μ L (the total absolute number of polymorphonuclear neutrophils plus bands) increase susceptibility to infection in a linear fashion (i.e., the lower the neutrophil count, the greater the degree of susceptibility)¹⁸ (see Fig. 53.1). Although most research studies use 500 cells/ μ L as an arbitrary definition of neutropenia, intensivists must recognize that susceptibility increases as the neutrophil count declines below 500 to 1000 cells/ μ L. A patient with a neutrophil

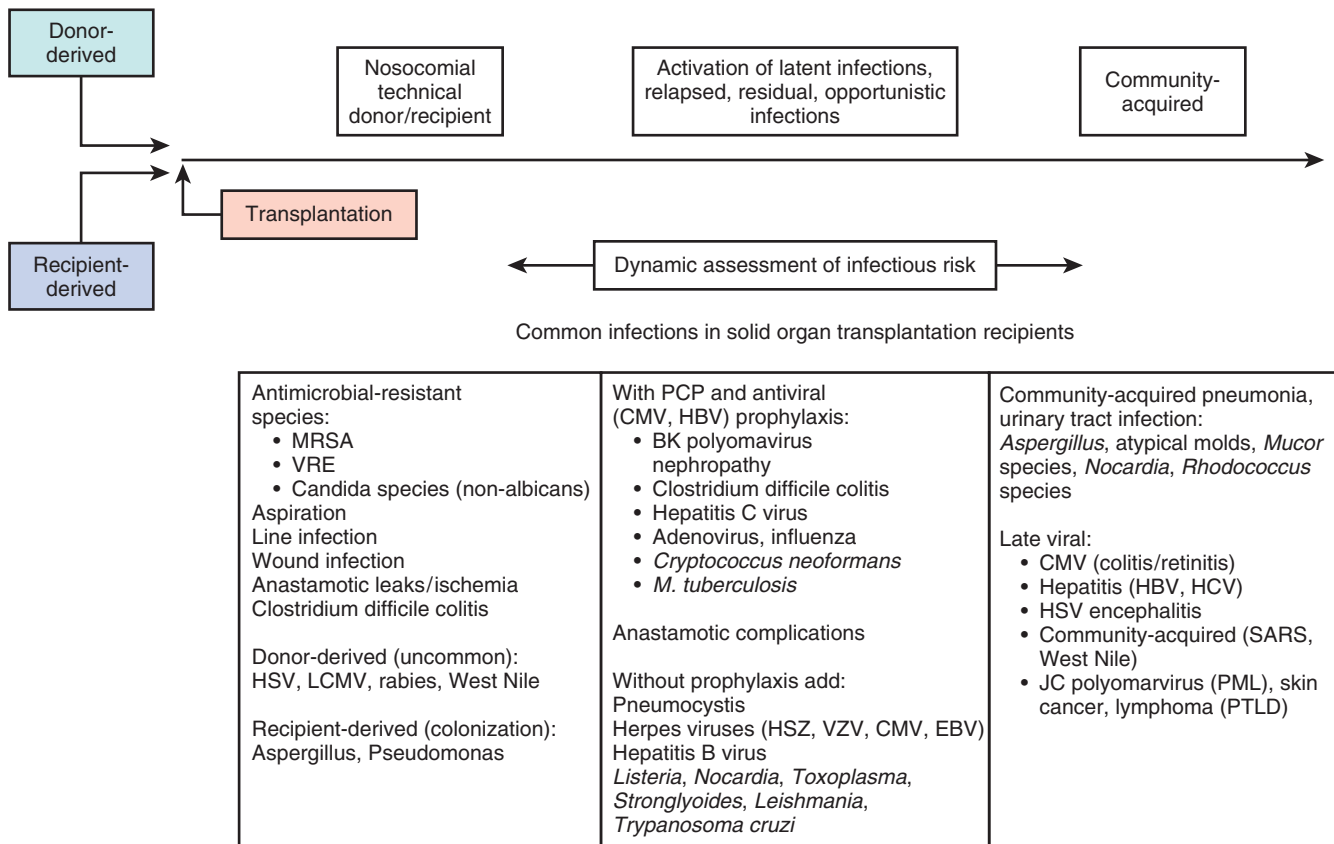

Figure 53.8 Usual sequence of infection after solid organ transplantation. (From Fishman JA: Infection in the solid organ transplant recipient. In Basow DS (ed): UpToDate. Waltham, MA, UpToDate, 2012.)

count of 100 cells/ μ L is much more vulnerable to infection than a patient with 500 or 1000 cells/ μ L, and a patient with zero neutrophils is at much higher risk for fulminant infection than a patient with 50 or 100 cells/ μ L. The trajectory of the neutrophil count is also important: a patient with a neutrophil count of 1500 cells/ μ L whose counts are dropping precipitously should best be treated like a patient with absolute neutropenia. Similarly, a patient with 500 neutrophils/ μ L whose counts are rising quickly is not nearly as vulnerable to a poor outcome as a patient with a count of 500 neutrophils/ μ L that is stable.

Patients with neutropenia are generally divided into high-risk and low-risk patients based on their likelihood of developing severe infectious complications. Markers for high risk include neutropenia for more than 7 days' duration and neutrophil count less than 100 cells/ μ L, as well as obvious signs of a life-threatening process such as hypotension, obtundation, pneumonia, or severe abdominal pain. As Figures 53.2 to 53.4 outline, this risk assessment is used in designating empiric regimens.

Thus, although the absolute neutrophil count is an essential factor to follow, the duration of neutropenia, the functional capability of neutrophils, the integrity of physical barriers such as the skin and gastrointestinal mucosa, the patient's microbiologic environment (endogenous and exogenous flora), and the status of other immune mechanisms also contribute to the infectious syndromes that will develop.

In the 1960s and 1970s, aerobic gram-negative bacilli such as *Escherichia coli*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa* predominated as pathogens in neutropenic patients. In the 1990s the spectrum of causative pathogens in neutropenic patients shifted from a predominance of gram-negative bacilli to a majority of gram-positive cocci including streptococci, staphylococci (including oxacillin-resistant *Staphylococcus aureus*), and enterococci (including vancomycin-resistant *enterococci*).^{10,12-15,19-21} *Candida* species have also become more frequent as pathogens, especially as patients are on broad-spectrum antibacterials and have long-term venous access devices in place.

More recently, highly resistant gram-negative bacilli have become major threats for nosocomial transmission. Clinicians must consider the possibility that a patient may be colonized and then infected with a *Stenotrophomonas*, a *Burkholderia*, or a carbapenemase-producing gram-negative Enterobacteriaceae such as a *Klebsiella*, an *Enterobacter*, or an *E. coli* that has developed mechanisms that evade currently marketed drugs.²²⁻²⁶

The management of febrile, neutropenic fever is reviewed in a guideline that is widely used to direct care in North America.⁶ Figures 53.2 to 53.4 summarize important aspects of management. Table 53.3 also provides a summary of useful management information. Table 53.4 outlines common prevention strategies that will modify the spectrum of causative pathogens. Box 53.1 summarizes the organisms that most often cause disease in neutropenic patients.

Table 53.4 Prevention of Infectious Complications in Compromised Patients

Method/Agent to Prevent Acquisition of, Suppress, or Eliminate Microbial Flora	Description/Example
Isolation	Total protective isolation with high-efficiency particulate air filters and absorbable or nonabsorbable antibiotics for bone marrow transplant recipient
Prophylactic antibacterial drugs	
Ciprofloxacin	Reduce bacterial infections in neutropenic patients
Trimethoprim-sulfamethoxazole	Suppress flora in patients with chronic bronchitis
Penicillin	Reduce frequency of streptococcal infections after splenectomy or in rheumatic valvular disease or graft-versus-host disease
Clarithromycin	Prevention of <i>Mycobacterium avium</i> complex infection in patients with advanced HIV disease
Isoniazid	Prevention of tuberculosis in PPD-positive individuals
Nonabsorbable broad-spectrum agents (i.e., aminoglycoside, plus bacitracin)	Gut decontamination for neutropenic patients
Prophylactic antiviral drugs	
Oral acyclovir or valganciclovir, or IV ganciclovir	Reduce frequency of CMV disease after transplantation
Rimantadine, oseltamivir	Prevent influenza
Prophylactic antifungal drugs	
Fluconazole	Prevent recurrent candidiasis
Liposomal amphotericin B or voriconazole or caspofungin	Prevent <i>Candida</i> or mold infections
Trimethoprim-sulfamethoxazole	Prevent <i>Pneumocystis</i> pneumonia
Prophylactic antiprotozoal/anthelmintic drugs	
Albendazole or ivermectin	Prevent disseminated strongyloidiasis in high-risk patients
Augmentation of host defenses	
Immunization	Pneumococcal and <i>Haemophilus</i> vaccine for patients before splenectomy
Immune serum globulin	Augment levels in deficient patients (e.g., common variable immunodeficiency)
Fresh frozen plasma	Augment complement levels in deficient patients
Neutrophil transfusions	Augment inflammatory response in neutropenic patients or patients with chronic functional neutrophil disorders
Lymphocyte or other mononuclear cell transfusions	Experimental therapies for tumors, various immunodeficiencies
Bone marrow or stem cell transplantation	Reconstitute patients with congenital immunodeficiencies or certain acquired cytopenias
Bone marrow human stem cell stimulation	G-CSF or GM-CSF to increase neutrophil or mononuclear cell quantity and function
Gene therapy	Replace genes to allow normal function

AIDS, acquired immunodeficiency syndrome; CMV, cytomegalovirus; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-monocyte colony-stimulating factor; HIV, human immunodeficiency virus; PPD, purified protein derivative.

Patients with neutropenia are generally suspected of being infected if the clinical syndrome is consistent with infection, or if the temperature is at least 38.3° C on one occasion or 38.1° C on two separate occasions. An elevated temperature alone should trigger the institution of broad-spectrum antimicrobials in almost all situations. Given this emphasis of using temperature as an indicator for starting antimicrobial therapy, using a validated technique to measure temperature is important. Although pulmonary artery or urinary catheter thermistors appear to provide the most accurate measurement, most experienced ICUs use tympanic membrane thermistors. Rectal probes are avoided in order to reduce the induction of perirectal infections in neutropenic patients, and to reduce the potential for fecal pathogen transmission. As noted earlier, although fever is almost always a reason to start antimicrobial therapy in this patient population, the absence of fever should not be the grounds for avoiding antimicrobials if a patient has other symptoms or signs suggesting infection. The threshold for

starting antimicrobials should be very low, i.e., if there is a suspicion of infection, a broad-spectrum regimen should be started.

As noted earlier, the initial regimen should not be parsimonious in terms of spectrum. Because this population of patients is susceptible to a wide variety of bacterial and fungal pathogens, a very wide broad-spectrum regimen should be used. There are many potential regimens, each of which must be tailored to the local experience with the patient population and the hospital, specific patient factors such as evidence of prior colonization or recent antimicrobial therapy, and clinical manifestations suggesting infection. Popular regimens would include (1) meropenem or ceftipime or piperacillin-tazobactam for broad-spectrum antibacterial activity plus (2) vancomycin or daptomycin for staphylococcal infections^{27,28} plus (3) ciprofloxacin or moxifloxacin or aztreonam for broader gram-negative bacillus coverage. Many experienced clinicians would add an echinocandin for anti-*Candida* activity given the frequency of

Box 53.1 Common Bacterial Pathogens in Neutropenic Patients

Common Gram-Positive Pathogens

Coagulase-negative staphylococci
Staphylococcus aureus, including methicillin-resistant strains
Enterococcus species, including vancomycin-resistant strains
 Viridans group streptococci
Streptococcus pneumoniae
Streptococcus pyogenes

Common Gram-Negative Pathogens

Escherichia coli
Klebsiella species
Enterobacter species
Pseudomonas aeruginosa
Citrobacter species
Acinetobacter species
Stenotrophomonas maltophilia

Box 53.2 Indications for Addition of Antibiotics Active against Gram-Positive Organisms to Empiric Regimen for Fever and Neutropenia

Hemodynamic instability or other evidence of severe sepsis
 Pneumonia documented radiographically
 Positive blood culture for gram-positive bacteria, before final identification and availability of susceptibility testing results
 Clinical evidence suggestive of serious catheter-related infection (e.g., chills or rigors with infusion through catheter, cellulitis around the catheter entry/exit site)
 Skin or soft tissue infection at any site
 Colonization with methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant enterococci, or penicillin-resistant *Streptococcus pneumoniae*
 Severe mucositis, if fluoroquinolone prophylaxis has been given and ceftazidime is used for empiric therapy

From Freifeld AG, Bow EJ, Sepkowitz KA, et al: Clinical practice guideline for the use of antimicrobial agents in neutropenic patients with cancer: 2010 update by the Infectious Diseases Society of America. Clin Infect Dis 2011;52:e56-e93, used by permission of Oxford University Press.

intravascular catheter-associated infections due to *Candida* species.²⁹⁻³³ Intensivists need to work closely with their infectious disease consultants, microbiology laboratories, and referring teams to develop regimens that are optimal for their hospital environment, for the patient population involved, and for the specific, unique patient who is being managed.

Empiric antiviral therapy is not usually initiated unless there is a specific reason to suspect a viral process. Antiviral agents would generally be added only if a specific viral process such as CMV colitis or disseminated herpes simplex were suspected.

For the duration of neutropenia (when the neutropenia is expected to be time-limited), broad-spectrum therapy must be continued. When a specific causative organism is identified, antimicrobial therapy should be optimized for that organism. However, unlike other immunologically normal patients, the broad-spectrum “background” (i.e., meropenem or piperacillin-tazobactam or cefepime or ceftazidime) must be continued until the neutropenia resolves, on the assumption that a patient who develops one infection is likely to develop or manifest another infectious process while the neutropenia persists.

Coverage for methicillin-resistant *Staphylococcus aureus* (MRSA) does not necessarily need to be continued if no MRSA is identified. There are environmental advantages to reducing vancomycin exposure.

As noted previously, there is no documented reason, even in this population, to use combination therapy to treat a specific pathogen in most situations, although combination therapy is needed for the empiric approach for the duration of neutropenia (Box 53.2). In rare situations, if the causative organism is not susceptible to agents with well-documented efficacy, combination therapy may be an appropriate strategy out of desperation. As an example, for

treating enteric carbapenemase-producing organisms, a combination of tigecycline plus colistin plus an aminoglycoside might be desirable given the high minimum inhibitory concentrations for all antibiotics for these organisms and the dreadful clinical results with any therapeutic intervention.³⁴⁻³⁸

For patients with fever and neutropenia, the cause of the fever is historically documented in only 50% to 60% of patients. The duration of therapy once empiric antimicrobials are started depends on the evolution of the neutrophil count, the patient's clinical status, and the results of diagnostic tests. If the patient defervesces and looks clinically well, however, the broad-spectrum regimen should not be stopped until the neutrophil count is above 500 to 750 cells/ μ L, preferably on two occasions, and the patient has received at least 10 to 14 days of therapy.

If a neutropenic patient is started on antibacterial therapy without fungal therapy, and defervescence has not occurred by days 3 to 5, an antifungal agent should be added (Figs. 53.3 and 53.4). The choice of antifungal agent depends on the patient population and the patient's specific history. In the current era many patients have been receiving short- or long-term prophylaxis with fluconazole, voriconazole, or posaconazole. Although in general clinicians could add fluconazole, an echinocandin (e.g., caspofungin or micafungin or anidulofungin) or liposomal amphotericin B can also be used. An echinocandin is often a preferred choice if the patient has been on long-term azole prophylaxis and if a mold infection is not suspected.³⁹⁻⁴²

As patients receive chemoprophylaxis with quinolones or azoles during periods of intense neutropenia or immunosuppression, breakthrough pathogens are more and more likely to be resistant to the prophylactic agents.^{40,42} Thus empiric regimens must be chosen with keen attention to the drugs that patients have received in the recent past,

as well as pathogens they have previously been colonized or infected with.

DIAGNOSTIC APPROACH

Patients with fever and neutropenia require aggressive diagnostic efforts to identify the cause of fever so that the appropriate antimicrobial agent is used and appropriate procedures (e.g., surgical drainage, removal of a foreign body such as a catheter) can be performed. All febrile neutropenic patients should at a minimum have two blood cultures drawn, with one drawn peripherally and one drawn through the lumen of the indwelling catheter that has either been in the longest or is most suspicious for being infected. Other sites should be cultured as clinically indicated.

Regular physical examination is necessary to identify sites that merit more focused investigation. With impaired inflammatory response, findings on examination may be subtle. Knowledge of the specific immunologic defect is important so that when cultures of blood, sputum, urine, or other appropriate body fluids or body sites are performed, special microbiologic approaches can be used to detect viruses, fungi, helminths, protozoa, and bacteria as indicated by the clinical situation. Imaging studies are also important because intra-abdominal, intrathoracic, intracerebral, and musculoskeletal processes can be clinically subtle and may not be associated with identifiable organisms in the bloodstream. A growing array of antigen detection systems and molecular and high-performance chromatographic tests are being investigated to facilitate diagnosis.

Some of these approaches, despite their promising initial reports, are not yet clinically practical because of their level of sensitivity, specificity, or the cost or expertise required to perform them adequately. For instance, the PCR test for *Pneumocystis* is so sensitive that there is no clear separation of patients who are colonized with *Pneumocystis* (and whose pulmonary dysfunction is due to another process), and the serum β -glucan antigen detection system is so nonspecific that some clinicians are not confident that the test provides useful information.⁴³⁻⁴⁵ Similarly, the PCR test for respiratory syncytial virus (RSV) or influenza or parainfluenza is so sensitive that immunosuppressed patients may shed small quantities of virus for many weeks after acute infection, confusing the diagnosis of the new pulmonary processes that occur after the acute viral infection is over, and at a time when another process is causing fever or pulmonary manifestations. Thus, these new tests must be interpreted with caution.

EMPIRIC AND SPECIFIC ANTIMICROBIAL THERAPY

Outside the ICU, stable patients with fever and neutropenia, and no obvious source of infection, are treated with a broad-spectrum regimen, as mentioned previously, that covers all likely pathogens. Recommended regimens for the “backbone” agent include a carbapenem with antipseudomonas activity (e.g., meropenem or imipenem), a β -lactam β -lactamase combination with antipseudomonas activity (e.g., piperacillin-tazobactam), and a broad-spectrum cephalosporin with antipseudomonas activity (e.g., ceftazidime). Although vancomycin is not necessarily indicated for empiric therapy of fever and neutropenia, in the ICU an antistaphylococcal drug (e.g., vancomycin or

daptomycin) is usually added if the patient has a long-term intravascular catheter in place and may be appropriate empirically in every patient who merits ICU admission until the causative pathogen is known. Because patients with fever and neutropenia have almost always had extensive exposure to hospital-acquired pathogens and to antimicrobials, clinicians must adjust the empiric regimens to fit the patient’s situation. Adding colistin plus tigecycline empirically might be appropriate for someone hospitalized during an outbreak of highly resistant *Acinetobacter* or *Klebsiella*.

Patients in the ICU are by definition either unstable hemodynamically or medically fragile due to concurrent disease. In such situations, many clinicians would expand antibacterial coverage with a second broad-spectrum drug (e.g., a quinolone such as ciprofloxacin), aztreonam, or an aminoglycoside (e.g., gentamicin or tobramycin).^{20,46-51}

A substantial number of febrile, neutropenic patients fail to improve in terms of fever or other manifestations. Once febrile and neutropenic patients are started on empiric therapy, if no causative process or organism is detected, one of the first three scenarios listed here is likely to be encountered. Figures 53.2 to 53.4 list some of the therapeutic options for such patients.

1. The patient defervesces and remains stable but the source remains unknown. In this case the empiric regimen is usually continued for a minimum of 7 to 10 days, and must be continued until the neutrophil count is over 500 to 1000 cells/ μ L unless no end is likely with the neutropenia.
2. The patient remains febrile and stable but the source remains unknown. Failure to improve may result from poor immune response, a need for drainage or necessity to remove foreign bodies, the use of drugs without activity against the causative organism, or a noninfectious process including drug allergy (i.e., fever resulting from a drug such as phenytoin or an antimicrobial agent). The potential causative processes need to be aggressively reassessed on a regular basis by physical examination, history, cultures, and imaging techniques. Most centers add antifungal therapy empirically at day 4 to day 7 of therapy if patients remain febrile.^{6,40,52} Fluconazole, liposomal amphotericin B, caspofungin, or voriconazole may be used: In some situations fluconazole would be less attractive either because the patient has received fluconazole prophylaxis or because molds are suspected.⁴¹ The toxicity profile of amphotericin B, even in its liposomal form, has led many clinicians to prefer voriconazole or one of the echinocandins (i.e., caspofungin, micafungin, or anidulafungin).^{32,53-56}
3. The patient deteriorates clinically but the source remains unknown. In this case continued evaluation for infectious and noninfectious sources of the infection should be pursued, and further empiric changes to the antimicrobial regimen should be considered.
4. The source of the infection is identified. The drug and the duration of therapy depend on the causative syndrome and microorganism. Table 53.3 lists some common scenarios. Rarely should the therapy be discontinued while the patient is neutropenic. Rarely is combination therapy necessary unless the causative organisms are multiple (suspected or confirmed) or (as described earlier)

the causative organism is not highly susceptible to available antimicrobial agents.^{12-16,18-21,49}

A common problem in febrile, neutropenic patients is managing indwelling intravascular lines.^{57,58} In general, these lines may be left in place initially if examination of the site reveals no indication of infection and the patient is hemodynamically stable. Blood cultures should be drawn through the catheter. Although some experts advocate drawing a culture through each port of each catheter, obtaining this many blood cultures is often not feasible because of time, cost, and volume of blood. If a patient is hemodynamically unstable and fails to respond promptly to fluid administration, it is prudent to remove the line in case an infected catheter is the source of the sepsis. Failure to remove the foreign body in this situation probably increases the likelihood of an unfavorable outcome. Should blood cultures become positive and should the suspicion be high that the catheter is the source, antibacterial therapy may be successful in some settings (e.g., if the pathogen is a bacterium that is relatively sensitive to antibacterial therapy), thus avoiding the need to remove the catheter. Situations suggesting that catheter removal is necessary include hemodynamic instability despite aggressive fluid resuscitation, tunnel infection, or infections resulting from fungi or relatively antibiotic-resistant bacteria such as *P. aeruginosa*.

Granulocyte transfusions have not been proved in randomized trials to improve survival in clinical settings probably because of the inability to administer a large number of cells with adequate frequency.^{16,17} However, many clinicians are convinced that matched white blood cell transfusions are helpful in managing life-threatening infections when patients are neutropenic and will use them when such cells are available. The manipulation of immune response with cytokines, cytokine inhibitors, or immunoglobulins is the subject of considerable investigation: Such interventions may reduce the duration of fever or the incidence of infections when used empirically, but in no setting have they been clearly shown to improve survival when administered after an infection has been documented. Algorithms for managing fever in neutropenic patients are provided in [Figures 53.2 to 53.4](#). [Table 53.3](#) suggests modifications of standard empiric regimens in certain common clinical scenarios.

PREVENTION OF INFECTION

Given the experience with frequent and severe infectious complications in cancer patients with neutropenia, it has been logical to attempt to prevent infection. Most microorganisms causing disease in this patient population arise from endogenous gastrointestinal, cutaneous, or respiratory flora. Total protected environments probably reduce frequency of infection, but this approach is expensive and inconvenient. Trying to prove a consistent beneficial impact on survival has been difficult, and thus such isolation is rarely used anymore. Some experts are enthusiastic about placing patients in positive-pressure rooms so that pathogens do not enter via particles and droplets from outside the room. This type of isolation has not clearly improved outcome, however, and is not a standard of care.^{59,60} In Europe, there is more enthusiasm for such an approach than in the United States. Controversies over interpretation

of data and concern that such antibiotic pressure will encourage the development of drug-resistant bacteria and fungi have diminished widespread acceptance in the United States.

Systemic antibacterial prophylaxis and systemic antifungal prophylaxis have been shown in some studies to reduce the number of infections, but their lack of effect on patient survival, their cost, and their impact on the emergence of resistance have made many clinicians reluctant to use them. Anti-*Pneumocystis* prophylaxis is, in contrast, highly effective in susceptible populations. Prophylaxis for CMV is rarely used unless the patient has received a solid organ or human stem cell transplant. [Table 53.4](#) summarizes general strategies of infection prevention in immunosuppressed patients including patients with neutropenia.

PATIENTS WITH HIV/AIDS

Opportunistic infections continue to occur in three groups of HIV-infected patients: (1) those who are unaware of their HIV status until they develop an opportunistic infection or tumor such as *Pneumocystis* pneumonia or *Toxoplasma* encephalitis or Kaposi sarcoma; (2) those who are unable or unwilling to receive appropriate therapy; and (3) those who fail antiretroviral therapy and opportunistic infection prophylaxis.^{4,61-65} In the United States, only about 20% to 40% of patients with HIV infection have a viral load under 50 copies/μL; thus, the majority of patients are not aware of their infection, not linked to care, or not able to adhere to an effective regimen.⁶⁶ It is notable that half of all HIV-infected patients are located in 12 large cities: in those areas, patients frequently come to emergency rooms and ICUs with opportunistic infections that are preventable with earlier antiretroviral therapy plus anti-infective chemoprophylaxis if these patients were successfully engaged in care.⁶⁷

Patients with HIV infection who are well controlled by antiretroviral drugs do not develop the classic complications of immunosuppression because their immunosuppression is subtle once their viral load is less than 50 copies/μL and their CD4 cell count rises, especially if it is greater than 200 cells/μL. Patients with CD4 counts greater than 200 cells/μL and viral loads less than 50 copies/μL may be seen in ICUs because of medical or surgical issues unrelated to their HIV infection. Such patients may also develop accelerated “processes of aging,” which include accelerated coronary artery disease, stroke, renal disease, or hepatic disease, but these processes appear to be related to enhanced chronic inflammation and not to immunosuppression.⁶⁸⁻⁷⁰

SPECTRUM OF CLINICAL MANIFESTATIONS

Patients with HIV infection develop clinical disease as a result of three basic processes: (1) opportunistic infections and tumors that are enabled by HIV-induced immunosuppression; (2) the direct effect of HIV on specific organs (e.g., cardiomyopathy, enteropathy, dementia); or (3) immunologically mediated processes (e.g., glomerulonephritis, thrombocytopenia).

MANAGEMENT OF ANTIRETROVIRAL DRUGS

For any HIV-infected patient in the ICU, clinicians must be cognizant of the need for careful management of

antiretroviral drugs.⁷¹ If patients are not receiving antiretroviral drugs at the time of ICU admission, the ICU is not a desirable setting for initiating them: patient commitment to long-term adherence is difficult to assess when patients are critically ill, and drug toxicities and interactions will be hard to assess.^{72,73} There is virtually no indication to start antiretroviral therapy acutely in the ICU following the diagnosis of an acute opportunistic infection with the rare exception of rapidly progressive forms of untreatable diseases such as JC virus encephalitis or cryptosporidiosis.

If patients enter the ICU already receiving antiretroviral therapy, an expert in HIV management should be consulted about the benefits of continuing the drugs rather than interrupting them. There is ample evidence that even brief interruption of antiretroviral drugs can have deleterious effects in terms of long-term loss of CD4 cells and in terms of the occurrence of opportunistic infections. However, administration of antiretroviral drugs in the ICU is challenging. Almost all commonly used antiretroviral drugs are available only in oral formulations, and thus absorption is often uncertain in critically ill patients. Subtherapeutic concentrations of antiretroviral drugs can select for drug resistance mutations, producing virus that is irrevocably nonsusceptible to the suboptimally dosed drug, sometimes with cross-class resistance. Many antiretroviral drugs affect cytochrome P-450 hepatic enzymes, resulting in altered pharmacokinetics for many non-AIDS-related drugs, which may substantially alter the efficacy or safety of the non-AIDS drug. Similarly, non-AIDS-related drugs can alter antiretroviral drug kinetics, resulting in drug serum levels that are above or below therapeutic targets, leading to viral resistance or drug toxicity. Stopping antiretroviral drugs may be the least harmful option. However, given the different half-lives of various antiretroviral agents, such discontinuation should be done in consultation with an HIV-experienced clinician.

Clinicians should refer to the Guidelines for Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents and the Guidelines for Antiretroviral Therapy in Adults and Adolescents for more detailed discussion on when to initiate antiretroviral therapy in the setting of a specific opportunistic infection.⁷⁴

DIAGNOSIS OF OPPORTUNISTIC INFECTIONS

The CD4⁺ T lymphocyte cell number continues to be a useful marker for predicting the occurrence of opportunistic infections in patients with HIV infection.⁵ This relationship of CD4⁺ T lymphocyte count to the occurrence of opportunistic infection continues to be as valid in the era of antiretroviral therapy as it was before the licensing of the first antiretroviral agent, zidovudine, in 1987.⁷⁵ Figure 53.5 demonstrates the typical relationship of CD4⁺ T lymphocyte counts to the occurrence of opportunistic infections. Knowledge of this relationship permits the focusing of diagnostic, therapeutic, and prophylactic management.

For instance, if a patient with HIV infection and a CD4⁺ T lymphocyte count of 700 cells/ μ L presents with diffuse pulmonary infiltrates, the diagnostic evaluation and empiric antimicrobial regimen should focus on common, nonopportunistic pathogens such as *Mycoplasma*, *Legionella*, and *Chlamydia* organisms, as well as common community-acquired viruses such as influenza plus opportunistic

infections that occur at high CD4⁺ T lymphocyte counts, such as *Mycobacterium tuberculosis* or *S. pneumoniae*. In contrast, if the same patient had a CD4⁺ T lymphocyte count fewer than 50 cells/ μ L, the evaluation and empiric regimen would focus on pneumocystosis, pneumococcal pneumonia, and tuberculosis, although the previously mentioned processes that occur at high CD4⁺ T lymphocyte counts can also occur at lower CD4⁺ T lymphocyte counts.

Keeping in mind that CD4⁺ T lymphocyte counts are useful predictors of susceptibility to infection is important, but they are not perfect. Occasionally, patients will develop opportunistic infections at “uncharacteristically” high CD4⁺ T lymphocyte counts. For instance, 5% to 10% of cases of pneumocystosis occur at CD4⁺ T lymphocyte counts greater than 200 cells/ μ L.⁷⁶ Clinical parameters can provide additional clues; for example, oral *candidiasis*, a previous opportunistic infection, a prior episode of pneumonia, or high viral load are independent risk factors for the occurrence of *Pneumocystis jiroveci* pneumonia (PCP), and logically for other infections as well.

A frequent question is whether an HIV-infected patient’s prior CD4⁺ T lymphocyte count nadir affects the likelihood of an opportunistic infection occurring if antiretroviral therapy has stimulated a CD4⁺ T lymphocyte count rise. Specifically, if a patient has a CD4⁺ T lymphocyte count of 400 cells/ μ L while receiving antiretroviral therapy and that patient’s CD4⁺ T lymphocyte count was 50 cells/ μ L before antiretroviral therapy, is that patient at greater risk for developing an opportunistic infection than another patient whose current CD4⁺ T lymphocyte count is 400 cells/ μ L but whose nadir before antiretroviral therapy was 250 cells/ μ L? The data suggest that these two patients have comparable risk (i.e., the current CD4⁺ T lymphocyte count is the most important predictor of risk and the earlier nadir has only minor influence on opportunistic infection susceptibility).

Like other immunosuppressed individuals, patients with HIV infection and low CD4⁺ T lymphocyte counts require a prompt attempt to define the specific cause of their clinical syndrome. Like patients with neutropenia, fevers of unknown origin are not common. However, patients often present with specific syndromes such as pneumonia, meningitis, focal neurologic abnormalities, chorioretinitis, or diarrhea. Patients can deteriorate quickly, and the range of causative organisms is broad. Thus, as with patients with neutropenia, HIV-infected individuals need specific microbiologic and pathologic tests to determine the specific cause of their syndrome so that the appropriate therapy can be initiated, and so that unnecessary drugs can be eliminated.

In evaluating the differential diagnosis of infectious syndromes in patients with HIV (and in every other patient population as well), geography is an important part of the history. Tuberculosis is always a concern because of the extraordinary susceptibility of HIV-infected patients for developing active disease once they have been exposed.⁷⁷⁻⁷⁹ It is notable, however, that although HIV and tuberculosis overlap in many patients in much of the developing world, in the United States only 10% of cases of tuberculosis occur in HIV-infected patients.⁸⁰ In many urban settings in the United States, each pulmonary evaluation should include smears and cultures for *M. tuberculosis*, both to diagnose the appropriate cause of the pulmonary dysfunction and to

assist in determining which respiratory precautions are appropriate. However, in the United States where only about 11,000 cases of new tuberculosis occur per year, and where 50% of cases occur in immigrants, the likelihood of tuberculosis in a U.S. native with no known exposure is quite low, in contrast to a recent immigrant from a highly endemic area.⁸⁰

In some areas of the country, such as the Ohio River Valley including Indianapolis, histoplasmosis is as common as pneumocystosis in causing diffuse pulmonary infiltrates. In the southwestern United States, coccidioidomycosis must be recognized as a cause of pulmonary infiltrates. The clinical presentations of tuberculosis, histoplasmosis, coccidioidomycosis, cryptococcosis, and toxoplasmosis can be clinically indistinguishable from PCP. Thus for HIV-infected patients with pulmonary infiltrates in an ICU, prolonged empiric therapy is discouraged in favor of vigorous efforts to establish a specific diagnosis.

CLINICAL SYNDROMES

HIV-infected patients are admitted to ICUs for major syndromes such as respiratory insufficiency, cerebral dysfunction, septic shock, hepatic or renal failure, and drug toxicities. However, patients with HIV infection also come to ICUs for routine procedures and routine postoperative care. In those situations their management ordinarily requires no extraordinary measures, with two exceptions, in addition to careful consideration of how to manage antiretroviral drugs.

First, as noted earlier, intensivists must consult with HIV specialists about management of antiretroviral drugs. The imprudent continuation of these drugs or the imprudent discontinuation of these drugs can have lifelong consequences for the patient that can be substantially avoided with proper consultation.

Second, drug interactions involving drugs used during procedures and certain antiretroviral drugs can have important clinical consequences. Many of the protease inhibitors and the non-nucleoside reverse transcriptase inhibitors that are now the backbone of antiretroviral therapy can inhibit or enhance the metabolism of drugs that depend on the cytochrome P-450 system. Thus, the half-lives of certain analgesics, sedatives, and hypnotics can be prolonged in HIV-infected patients who are taking ritonavir, for example. This pharmacokinetic effect is also relevant for a host of other therapeutic agents used in the ICU and may affect their efficacy or safety. Clinicians need to be familiar with these interactions when selecting new therapies for procedures or for clinical entities. Given how complicated these interactions are, consultation with a specialist, e.g., a pharmacologist or infectious disease specialist, is appropriate for any HIV patient admitted to the ICU when antiretroviral drugs are involved.

The therapies for specific opportunistic pathogens are summarized in [Table 53.5](#).

RESPIRATORY INSUFFICIENCY

Patients with HIV infection can develop severe pulmonary dysfunction because of common community-acquired pathogens such as *S. pneumoniae*, *Legionella*, *Mycoplasma*, and *Chlamydia*; adenovirus; influenza; or respiratory syncytial virus, as well as other opportunistic viruses and fungi. Thus

the diagnostic evaluation needs to be comprehensive, emphasizing direct smears of sputum or bronchoalveolar lavage. It is important to recognize that the clinical presentations produced by many causative agents can be similar. For instance, histoplasmosis, tuberculosis, and nonspecific interstitial pneumonitis can present identically to PCP.^{76,77,81,82} Thus although empiric diagnosis and empiric therapy may be reasonable as initial approaches to some patients with HIV infection and mild pneumonitis, such an approach is usually not appropriate for patients in an ICU.

Evaluation of induced sputum is the first step in the diagnostic approach to PCP. Sensitivity can be as high as 80% to 95% at many hospitals (at some institutions the yield is considerably lower).⁸³ Specificity should be 100% in an experienced laboratory. Other pathogens, including mycobacteria, fungi, and routine bacteria, can be identified in sputum as well. For intubated patients, respiratory secretions obtained by deep intratracheal suctioning are also likely to be useful, although they have not been as carefully studied as induced sputum. Should the diagnosis not be established by evaluation of sputum or intratracheal secretions, bronchoscopy should be performed. Bronchoalveolar lavage should diagnose almost 100% of cases of PCP, even if patients have already received 7 to 10 days of empiric therapy at the time of the diagnostic procedure.⁷⁶ A diagnosis of PCP is established by visualizing one or more clusters of organisms. Some laboratories are now using PCR to diagnose PCP, but this test is not standardized and is likely to be highly sensitive but not highly specific for identifying *Pneumocystis* as the cause of the pulmonary dysfunction.^{44,84}

Diagnostic criteria for other opportunistic infections are reviewed in Chapters 12 and 42. CMV merits special mention. CMV pneumonia almost never occurs in patients with HIV infection, as opposed to patients with solid organ or stem cell transplants. CMV should be considered the cause only if other causative processes have been ruled out, and there is convincing histologic or cytologic evidence. Culture of sputum or bronchoalveolar lavage for CMV does not provide useful information: in particular, patients with CD4⁺ T lymphocyte counts below 100 cells/μL will predictably have CMV present in their secretion independent of whether or not pulmonary disease is present.⁸⁵ A diagnosis of CMV pneumonia in this patient population is suggested by cytologic test and confirmed by the presence of multiple inclusion bodies in lung tissue obtained by transbronchial or open lung biopsy.

Similarly, *Mycobacterium avium* complex (MAC) and herpes simplex virus (HSV) can often be found in respiratory secretions of patients with HIV/AIDS by culture or by nucleic acid amplification tests, but these organisms almost never cause pneumonia in patients with HIV infection. In other patient populations they can clearly cause pneumonia, but the dearth of CMV, MAC, and HSV pneumonia in this patient population emphasizes the point that it is important to know from published literature what the clinical likelihood is for different microbial processes.

Fungal pneumonias other than PCP are generally diagnosed by direct microscopy or culture of respiratory secretions (sputum or bronchoalveolar lavage). *Candida* organisms almost never cause pneumonia in patients with HIV infection. The frequency of *Cryptococcus*, *Histoplasma*,

Table 53.5 Treatment of AIDS-Associated Opportunistic Infections

Opportunistic Infection	Preferred Therapy	Alternative Therapy	Other Comments
<i>Pneumocystis pneumonia (PCP)</i>	<p>Patients who develop PCP despite TMP-SMX prophylaxis can usually be treated with standard doses of TMP-SMX</p> <p>Duration of PCP treatment: 21 days</p> <p><i>For Moderate to Severe PCP:</i></p> <p>TMP-SMX: (TMP 15-20 mg and SMX 75-100 mg/kg/day) IV given q6h or q8h may switch to PO after clinical improvement</p> <p><i>For Mild to Moderate PCP:</i></p> <p>TMP-SMX: (TMP 15-20 mg and SMX 75-100 mg/kg/day), given PO in 3 divided doses, or</p> <p>TMP-SMX: (160 mg/800 mg or DS) 2 tablets PO tid</p> <p><i>Secondary Prophylaxis, after completion of PCP treatment:</i></p> <p>TMP-SMX DS: 1 tablet PO daily or</p> <p>TMP-SMX (80 mg/400 mg or SS): 1 tablet PO daily</p>	<p><i>For Moderate to Severe PCP:</i></p> <p>Pentamidine 4 mg/kg IV daily infused over ≥60 minutes; can reduce dose to 3 mg/kg IV daily because of toxicities, or</p> <p>Primaquine 30 mg (base) PO daily + (clindamycin 600 mg q6h IV or 900 mg IV q8h) or (clindamycin 300 mg PO q6h or 450 mg PO q8h)</p> <p><i>For Mild to Moderate PCP:</i></p> <p>Dapsone 100 mg PO daily + TMP 5 mg/kg PO tid, or</p> <p>Primaquine 30 mg (base) PO daily + (clindamycin 300 mg PO q6h or 450 mg PO q8h), or</p> <p>Atovaquone 750 mg PO bid with food</p> <p><i>Secondary Prophylaxis, after completion of PCP treatment:</i></p> <p>TMP-SMX DS: 1 tablet PO tid, or</p> <p>Dapsone 100 mg PO daily, or</p> <p>Dapsone 50 mg PO daily + (pyrimethamine 50 mg + leucovorin 25 mg) PO weekly, or (Dapsone 200 mg + pyrimethamine 75 mg + leucovorin 25 mg) PO weekly, or</p> <p>Aerosolized pentamidine 300 mg monthly via Respirgard II nebulizer, or</p> <p>Atovaquone 1500 mg PO daily, or (Atovaquone 1500 mg + pyrimethamine 25 mg + leucovorin 10 mg) PO daily</p>	<p><i>Indications for Adjunctive Corticosteroids</i></p> <p>PaO₂ <70 mm Hg at room air, or</p> <p>Alveolar-arterial O₂ gradient >35 mm Hg</p> <p><i>Prednisone Doses (beginning as early as possible and within 72 hours of pcp therapy):</i></p> <p>Days 1-5: 40 mg PO bid</p> <p>Days 6-10: 40 mg PO daily</p> <p>Days 11-21: 20 mg PO daily</p> <p>IV methylprednisolone can be administered as 75% of prednisone dose.</p> <p>Benefit of corticosteroid if started after 72 hours of treatment is unknown, but some clinicians will use it for moderate-to-severe PCP.</p> <p>Whenever possible, patients should be tested for G6PD before use of dapsone or primaquine. Alternative therapy should be used in patients found to have G6PD deficiency.</p> <p>Patients who are receiving pyrimethamine/sulfadiazine for treatment or suppression of toxoplasmosis do not require additional PCP prophylaxis.</p> <p>If TMP-SMX is discontinued because of a mild adverse reaction, re-institution should be considered after the reaction resolves. The dose can be increased gradually (desensitization), reduced, or the frequency modified.</p> <p>TMP-SMX should be permanently discontinued in patients with possible or definite Stevens-Johnson syndrome or toxic epidermal necrosis.</p>

Toxoplasma gondii
encephalitis

Treatment of Acute Infection:
 Pyrimethamine 200 mg PO 1 time, followed by weight-based therapy:
 If <60 kg, pyrimethamine 50 mg PO once daily + sulfadiazine 1000 mg PO q6h + leucovorin 10-25 mg PO once daily
 If ≥60 kg, pyrimethamine 75 mg PO once daily + sulfadiazine 1500 mg PO q6h + leucovorin 10-25 mg PO once daily
 Leucovorin dose can be increased to 50 mg daily or bid

Duration for Acute Therapy:
 At least 6 weeks; longer duration if clinical or radiologic disease is extensive or response is incomplete at 6 weeks

Chronic Maintenance Therapy:
 Pyrimethamine 25-50 mg PO daily + sulfadiazine 2000-4000 mg PO daily (in 2-4 divided doses) + leucovorin 10-25 mg PO daily (AI)

Treatment of Acute Infection:
 Pyrimethamine (leucovorin)* + clindamycin 600 mg IV or PO q6h or
 TMP-SMX (TMP 5 mg/kg and SMX 25 mg/kg) IV or PO bid, or
 Atovaquone 1500 mg PO bid with food + pyrimethamine (leucovorin), or
 Atovaquone 1500 mg PO BID with food + sulfadiazine 1000-1500 mg PO q6h (weight-based dosing, as in preferred therapy) or
 Atovaquone 1500 mg PO bid with food, or
 Pyrimethamine (leucovorin)* + azithromycin 900-1200 mg PO daily

Chronic Maintenance Therapy:
 Clindamycin 600 mg PO q8h + (pyrimethamine 25-50 mg + leucovorin 10-25 mg) PO daily or
 TMP-SMX DS 1 tablet bid, or
 Atovaquone 750-1500 mg PO bid + (pyrimethamine 25 mg + leucovorin 10 mg) PO daily, or
 Atovaquone 750-1500 mg PO bid + sulfadiazine 2000-4000 mg PO daily (in 2-4 divided doses), or
 Atovaquone 750-1500 mg PO bid with food
 *Pyrimethamine and leucovorin doses are the same as for preferred therapy.

Adjunctive corticosteroids (e.g., dexamethasone) should only be administered when clinically indicated to treat mass effect associated with focal lesions or associated edema; discontinue as soon as clinically feasible. Anticonvulsants should be administered to patients with a history of seizures and continued through acute treatment, but should not be used as seizure prophylaxis. If clindamycin is used in place of sulfadiazine, additional therapy must be added to prevent PCP.

Table 53.5 Treatment of AIDS-Associated Opportunistic Infections (Continued)

Opportunistic Infection	Preferred Therapy	Alternative Therapy	Other Comments
<i>Mycobacterium tuberculosis</i> disease (TB)	<p>After collecting specimen for culture and molecular diagnostic tests, empiric TB treatment should be started in individuals with clinical and radiographic presentation suggestive of TB.</p> <p>Refer to Table 53.3 for dosing recommendations.</p> <p>Initial Phase (2 months, given daily, 5-7 times/week by DOT): INH + [RIF or RFB] + PZA + EMB</p> <p>Continuation Phase: INH + (RIF or RFB) daily (5-7 times/week) or <i>tiv</i></p> <p>Total Duration of Therapy (for drug-susceptible TB):</p> <p>Pulmonary TB: 6 months</p> <p>Pulmonary TB and culture-positive after 2 months of TB treatment: 9 months</p> <p>Extrapulmonary TB w/CNS infection: 9-12 months;</p> <p>Extrapulmonary TB w/bone or joint involvement: 6 to 9 months;</p> <p>Extrapulmonary TB in other sites: 6 months</p> <p>Total duration of therapy should be based on number of doses received, not on calendar time</p>	<p>Treatment for Drug-Resistant TB Resistant to INH: (RIF or RFB) + EMB + PZA + (moxifloxacin or levofloxacin) for 2 months; followed by (RIF or RFB) + EMB + (moxifloxacin or levofloxacin) for 7 months</p> <p>Resistant to Rifamycins ± Other Drugs: Regimen and duration of treatment should be individualized based on resistance pattern, clinical and microbiologic responses, and in close consultation with experienced specialists</p>	<p>Adjunctive corticosteroid improves survival for TB meningitis and pericarditis. See text for drug, dose, and duration recommendations.</p> <p>RIF is <i>not recommended</i> for patients receiving HIV PI because of its induction of PI metabolism.</p> <p>RFB is a less potent CYP3A4 inducer than RIF and is preferred in patients receiving PIs.</p> <p>Once weekly rifapentine can result in development of rifamycin resistance in HIV-infected patients and is <i>not recommended</i>.</p> <p>Therapeutic drug monitoring should be considered in patients receiving rifamycin and interacting ART.</p> <p>Paradoxical IRIS that is not severe can be treated with NSAIDs without a change in TB or HIV therapy.</p> <p>For severe IRIS reaction, consider prednisone and taper over 4 weeks based on clinical symptoms. For example: <i>If receiving RIF:</i> prednisone 1.5 mg/kg/day for 2 weeks, then 0.75 mg/kg/day for 2 weeks <i>If receiving RFB:</i> prednisone 1.0 mg/kg/day for 2 weeks, then 0.5 mg/kg/day for 2 weeks</p> <p>A more gradual tapering schedule over a few months may be necessary for some patients.</p>
Disseminated <i>Mycobacterium avium</i> complex (MAC) disease	<p>At Least 2 Drugs as Initial Therapy with:</p> <p>Clarithromycin 500 mg PO bid + ethambutol 15 mg/kg PO daily, or</p> <p>Azithromycin 500-600 mg + ethambutol 15 mg/kg PO daily if drug interaction or intolerance precludes the use of clarithromycin</p> <p>Duration:</p> <p>At least 12 months of therapy, can discontinue if no signs and symptoms of MAC disease and sustained (>6 months) CD4 count >100 cells/μL in response to ART</p>	<p>Addition of a third or fourth drug should be considered for patients with advanced immunosuppression (CD4 counts <50 cells/μL), high mycobacterial loads (>2 log CFU/mL of blood), or in the absence of effective ART.</p> <p>Third or Fourth Drug Options May Include:</p> <p>RFB 300 mg PO daily (dosage adjustment may be necessary based on drug interactions),</p> <p>Amikacin 10-15 mg/kg IV daily, or</p> <p>Streptomycin 1 g IV or IM daily, or</p> <p>Moxifloxacin 400 mg PO daily or levofloxacin 500 mg PO daily</p>	<p>Testing of susceptibility to clarithromycin and azithromycin is recommended.</p> <p>NSAIDs can be used for patients who experience moderate to severe symptoms attributed to IRIS.</p> <p>If IRIS symptoms persist, short-term (4-8 weeks) systemic corticosteroids (equivalent to 20-40 mg prednisone) can be used.</p>

Bacterial respiratory diseases (with focus on pneumonia)

Empiric antibiotic therapy should be initiated promptly for patients presenting with clinical and radiographic evidence consistent with bacterial pneumonia. The recommendations listed are suggested empiric therapy. The regimen should be modified as needed once microbiologic results are available.	Empiric antibiotic therapy should be used with caution in patients in whom TB is suspected but is not being treated. Empiric therapy with a macrolide alone is not routinely recommended, because of increasing pneumococcal resistance.
<p>Empiric Outpatient Therapy: A PO β-lactam + a PO macrolide (azithromycin or clarithromycin) Preferred β-lactams: high-dose amoxicillin or amoxicillin/clavulanate Alternative β-lactams: cefpodoxime or cefuroxime, or</p> <p>For penicillin-allergic patients: Levofloxacin 750 mg PO once daily, or moxifloxacin 400 mg PO once daily Duration: 7–10 days (a minimum of 5 days). Patients should be afebrile for 48–72 hours and clinically stable before stopping antibiotics.</p> <p>Empiric Therapy for Non-ICU Hospitalized Patients: An IV β-lactam + a macrolide (azithromycin or clarithromycin) Preferred β-lactams: ceftriaxone, cefotaxime, or ampicillin-sulbactam For penicillin-allergic patients: Levofloxacin, 750 mg IV once daily, or moxifloxacin, 400 mg IV once daily Empiric Therapy for ICU Patients: An IV β-lactam + IV azithromycin, or An IV β-lactam + (levofloxacin 750 mg IV once daily or moxifloxacin 400 mg IV once daily)</p> <p>Preferred β-lactams: ceftriaxone, cefotaxime, or ampicillin-sulbactam Empiric Therapy for Patients at Risk of Pseudomonas Pneumonia: An IV antipseudomococcal, antipseudomonal β-lactam + ciprofloxacin 400 mg IV q8–12h or levofloxacin 750 mg IV once daily Preferred β-lactams: piperacillin-tazobactam, ceftazidime, imipenem, or meropenem</p> <p>Empiric Therapy for Patients at Risk for Methicillin-Resistant Staphylococcus aureus Pneumonia: Add vancomycin IV or linezolid (IV or PO) to the baseline regimen Addition of clindamycin to vancomycin (but not to linezolid) can be considered for severe necrotizing pneumonia to minimize bacterial toxin production</p>	<p>Empiric Outpatient Therapy: A PO β-lactam + PO doxycycline Preferred β-lactams: high-dose amoxicillin or amoxicillin/clavulanate Alternative β-lactams: cefpodoxime or cefuroxime</p> <p>Empiric Therapy for Non-ICU Hospitalized Patients: An IV β-lactam + doxycycline Empiric Therapy for ICU Patients: For penicillin-allergic patients: Aztreonam IV + (levofloxacin 750 mg IV once daily or moxifloxacin 400 mg IV once daily) Empiric Therapy for Patients at Risk of Pseudomonas Pneumonia: An IV antipseudomococcal, antipseudomonal β-lactam + an aminoglycoside + azithromycin, or Above β-lactam + an aminoglycoside + (levofloxacin 750 mg IV once daily or moxifloxacin 400 mg IV once daily), or For penicillin-allergic patients: Replace the β-lactam with aztreonam</p>

Table 53.5 Treatment of AIDS-Associated Opportunistic Infections (Continued)

Opportunistic Infection	Preferred Therapy	Alternative Therapy	Other Comments
Cryptococcosis	<p><i>Cryptococcal Meningitis</i> <i>Induction Therapy (for at least 2 weeks, followed by consolidation therapy):</i> Liposomal amphotericin B 3-4 mg/kg IV daily + flucytosine 25 mg/kg PO qid (Note: Flucytosine dose should be adjusted in patients with renal dysfunction.)</p> <p><i>Consolidation Therapy (for at least 8 weeks followed by maintenance therapy):</i> Fluconazole 400 mg PO (or IV) daily</p> <p><i>Maintenance therapy:</i> Fluconazole 200 mg PO daily for at least 12 months</p> <p><i>For Non-CNS, Extrapulmonary Cryptococcosis and Diffuse Pulmonary Disease:</i> Treatment same as for cryptococcal meningitis</p> <p><i>Non-CNS Cryptococcosis with Mild to Moderate Symptoms and Focal Pulmonary Infiltrates:</i> Fluconazole, 400 mg PO daily for 12 months</p>	<p><i>Cryptococcal Meningitis</i> <i>Induction Therapy (for at least 2 weeks, followed by consolidation therapy):</i> Amphotericin B deoxycholate 0.7 mg/kg IV daily + flucytosine 25 mg/kg PO qid, or Amphotericin B lipid complex 5 mg/kg IV daily + flucytosine 25 mg/kg PO qid, or Liposomal amphotericin B 3-4 mg/kg IV daily + fluconazole 800 mg PO or IV daily, or Amphotericin B deoxycholate 0.7 mg/kg IV daily + fluconazole 800 mg PO or IV daily, or</p> <p>Fluconazole 400-800 mg PO or IV daily + flucytosine 25 mg/kg PO qid, or Fluconazole 1200 mg PO or IV daily</p> <p><i>Consolidation Therapy (for at least 8 weeks followed by maintenance therapy):</i> Itraconazole 200 mg PO bid for 8 weeks—less effective than fluconazole</p> <p><i>Maintenance therapy:</i> No alternative therapy recommendation</p>	<p>Addition of flucytosine to amphotericin B has been associated with more rapid sterilization of CSF and decreased risk for subsequent relapse.</p> <p>Patients receiving flucytosine should have either blood levels monitored (peak level 2 hours after dose should be 30-80 µg/mL) or close monitoring of blood counts for development of cytopenia. Dosage should be adjusted in patients with renal insufficiency.</p> <p>Opening pressure should always be measured when an LP is performed. Repeated LPs or CSF shunting are essential to effectively manage increased intracranial pressure.</p> <p>Corticosteroids and mannitol are ineffective in reducing ICP and are <i>not</i> recommended.</p> <p>Some specialists recommend a brief course of corticosteroid for management of severe IRIS symptoms.</p>

Histoplasmosis	<p>Moderately Severe to Severe Disseminated Disease Induction Therapy (for at least 2 weeks or until clinically improved):</p> <p>Liposomal amphotericin B 3 mg/kg IV daily</p> <p>Maintenance Therapy</p> <p>Itraconazole 200 mg PO tid for 3 days, then 200 mg PO bid</p> <p>Less Severe Disseminated Disease Induction and Maintenance Therapy:</p> <p>Itraconazole 200 mg PO tid for 3 days, then 200 mg PO bid</p> <p>Duration of Therapy:</p> <p>At least 12 months</p> <p>Meningitis</p> <p>Induction Therapy (4-6 weeks):</p> <p>Liposomal amphotericin B 5 mg/kg/day</p> <p>Maintenance Therapy:</p> <p>Itraconazole 200 mg PO bid to tid for ≥1 year and until resolution of abnormal CSF findings</p> <p>Long-Term Suppression Therapy:</p> <p>For patients with severe disseminated or CNS infection after completion of at least 12 months of therapy; and those who relapse despite appropriate therapy</p> <p>Itraconazole 200 mg PO daily</p>	<p>Moderately Severe to Severe Disseminated Disease Induction Therapy (for at least 2 weeks or until clinically improved):</p> <p>Amphotericin B lipid complex 3 mg/kg IV daily, or</p> <p>Amphotericin B cholesteryl sulfate complete 3 mg/kg IV daily</p> <p>Alternatives to Itraconazole for Maintenance Therapy or Treatment of Less Severe Disease:</p> <p>Voriconazole 400 mg PO bid for 1 day, then 200 mg bid, or</p> <p>Posaconazole 400 mg PO bid</p> <p>Fluconazole 800 mg PO daily</p> <p>Meningitis:</p> <p>No alternative therapy recommendation</p> <p>Long-Term Suppression Therapy:</p> <p>Fluconazole 400 mg PO daily</p>	<p>Itraconazole, posaconazole, and voriconazole may have significant interactions with certain ARV agents. These interactions are complex and can be bidirectional. Therapeutic drug monitoring and dosage adjustment may be necessary to ensure triazole antifungal and ARV efficacy and reduce concentration-related toxicities. Random serum concentration of itraconazole + hydroitraconazole should be >1 µg/mL. Clinical experience with voriconazole or posaconazole in the treatment of histoplasmosis is limited. Acute pulmonary histoplasmosis in HIV-infected patients with CD4 counts >300 cells/µL should be managed as nonimmunocompromised host.</p>

Table 53.5 Treatment of AIDS-Associated Opportunistic Infections (Continued)

Opportunistic Infection	Preferred Therapy	Alternative Therapy	Other Comments
Coccidioidomycosis	<p><i>Clinically Mild Infections</i> (e.g., focal pneumonia):</p> <p>Fluconazole 400 mg PO daily or Itraconazole 200 mg PO bid</p> <p><i>Severe, Nonmeningeal Infection</i> (diffuse pulmonary infection or severely ill patients with extrathoracic, disseminated disease):</p> <p>Amphotericin B deoxycholate 0.7–1.0 mg/kg IV daily</p> <p>Lipid formulation amphotericin B 4–6 mg/kg IV daily</p> <p>Duration of therapy: continue until clinical improvement, then switch to an azole</p> <p><i>Meningeal Infections:</i></p> <p>Fluconazole 400–800 mg IV or PO daily</p> <p><i>Chronic Suppressive Therapy:</i></p> <p>Fluconazole 400 mg PO daily, or Itraconazole 200 mg PO bid</p>	<p><i>Mild Infections</i> (focal pneumonia) for patients who failed to respond to fluconazole or itraconazole:</p> <p>Posaconazole 200 mg PO bid, or Voriconazole 200 mg PO bid</p> <p><i>Severe, Nonmeningeal Infection</i> (diffuse pulmonary infection or severely ill patients with extrathoracic, disseminated disease):</p> <p>Some specialists will add a triazole (fluconazole or itraconazole, with itraconazole preferred for bone disease) 400 mg per day to amphotericin B therapy and continue triazole once amphotericin B is stopped</p> <p><i>Meningeal Infections:</i></p> <p>Itraconazole 200 mg PO tid for 3 days, then 200 mg PO bid, or</p> <p>Posaconazole 200 mg PO bid, or</p> <p>Voriconazole 200–400 mg PO bid, or</p> <p>Intrathecal amphotericin B deoxycholate, when triazole antifungals are ineffective</p> <p><i>Chronic suppressive therapy:</i></p> <p>Posaconazole 200 mg PO bid, or</p> <p>Voriconazole 200 mg PO bid</p> <p><i>Alternative Therapy:</i></p> <p>Lipid formulation of amphotericin B 5 mg/kg IV daily, or</p> <p>Amphotericin B deoxycholate 1 mg/kg IV daily, or</p> <p>Caspofungin 70 mg IV 1 time, then 50 mg IV daily, or</p> <p>Micafungin 100–150 mg IV daily, or</p> <p>Anidulafungin 200 mg IV 1 time, then 100 mg IV daily, or</p> <p>Posaconazole 200 mg PO qid, then, after condition improved, 400 mg PO bid</p>	<p>Some patients with meningitis may develop hydrocephalus and require CSF shunting.</p> <p>Therapy should be continued indefinitely in patients with diffuse pulmonary or disseminated diseases because relapse can occur in 25–33% of HIV-negative patients. It can also occur in HIV-infected patients with CD4 counts >250 cells/μL</p> <p>Therapy should be lifelong in patients with meningeal infections because relapse occurs in 80% of HIV-infected patients after discontinuation of triazole therapy.</p> <p>Itraconazole, posaconazole, and voriconazole may have significant interactions with certain ARV agents. These interactions are complex and can be bidirectional.</p> <p>Therapeutic drug monitoring and dosage adjustment may be necessary to ensure triazole antifungal and antiretroviral efficacy and reduce concentration-related toxicities.</p> <p>Intrathecal amphotericin B should only be given in consultation with a specialist and administered by an individual with experience with the technique.</p> <p>Potential for significant pharmacokinetic interactions between certain ARV agents and voriconazole; they should be used cautiously in these situations. Consider therapeutic drug monitoring and dosage adjustment if necessary.</p>
Aspergillosis, invasive	<p><i>Preferred Therapy:</i></p> <p>Voriconazole 6 mg/kg IV q12h for 1 day, then 4 mg/kg IV q12h, followed by voriconazole 200 mg PO q12h after clinical improvement</p> <p><i>Duration of Therapy:</i></p> <p>Until CD4 cell count >200 cells/μL and the infection appears to be resolved</p>		

Cytomegalovirus (CMV) disease

Cytomegalovirus (CMV) disease	<p>CMV Retinitis Induction Therapy for Immediate Sight-Threatening Lesions (adjacent to the optic nerve or fovea) Consult ophthalmologist; ganciclovir implant no longer available: Ganciclovir 5 mg/kg IV q12h for 14-21 days followed by Valganciclovir 900 mg PO bid</p> <p>For Small Peripheral Lesions: Valganciclovir 900 mg PO bid for 14-21 days</p> <p>One dose of intravitreal ganciclovir can be administered immediately after diagnosis until steady state plasma ganciclovir concentration is achieved with oral valganciclovir</p> <p>Chronic Maintenance (secondary prophylaxis): Valganciclovir 900 mg PO daily (for small peripheral lesion).</p> <p>CMV Esophagitis or Colitis: Ganciclovir 5 mg/kg IV q12h; may switch to valganciclovir 900 mg PO q12h once patient can tolerate oral therapy Duration: 21-42 days or until symptoms have resolved</p> <p>Maintenance therapy is usually not necessary, but should be considered after relapses.</p> <p>Well-Documented, Histologically Confirmed CMV Pneumonia: Experience for treating CMV pneumonitis in HIV patients is limited. Use of IV ganciclovir or IV foscarnet is reasonable (doses same as for CMV retinitis) The optimal duration of therapy and the role of oral valganciclovir have not been established.</p> <p>CMV Neurologic Disease Note: Treatment should be initiated promptly. Ganciclovir 5 mg/kg IV q12h + (foscarnet 90 mg/kg IV q12h or 60 mg/kg IV q8h) to stabilize disease and maximize response, continue until symptomatic improvement and resolution of neurologic symptoms The optimal duration of therapy and the role of oral valganciclovir have not been established.</p>	<p>CMV Retinitis Induction Therapy: Ganciclovir 5 mg/kg IV q12h for 14-21 days, or Foscarnet 90 mg/kg IV q12h or 60 mg q8h for 14-21 days, or Cidofovir 5 mg/kg/week IV for 2 weeks; saline hydration before and after therapy and probenecid, 2 g PO 3 hours before dose, followed by 1 g PO 2 hours and 8 hours after the dose (total of 4 g). (Note: This regimen should be avoided in patients with sulfa allergy because of cross-hypersensitivity with probenecid.)</p> <p>Chronic Maintenance (secondary prophylaxis): Ganciclovir 5 mg/kg IV 5-7 times weekly, or Foscarnet 90-120 mg/kg IV once daily, or Cidofovir 5 mg/kg IV every other week with saline hydration and probenecid as above</p> <p>CMV Esophagitis or Colitis: Foscarnet 90 mg/kg IV q12h or 60 mg/kg q8h for patients with treatment-limiting toxicities to ganciclovir or with ganciclovir resistance, or Valganciclovir 900 mg PO q12h in milder disease and if able to tolerate PO therapy, or For mild cases, if ART can be initiated without delay, consider withholding CMV therapy. Duration: 21-42 days or until symptoms have resolved</p>	<p>The choice of therapy for CMV retinitis should be individualized, based on location and severity of the lesions, level of immunosuppression, and other factors (e.g., concomitant medications and ability to adhere to treatment).</p> <p>The choice of chronic maintenance therapy (route of administration and drug choices) should be made in consultation with an ophthalmologist. Considerations should include the anatomic location of the retinal lesion, vision in the contralateral eye, the patients' immunologic and virologic status and response to ART. Patients with CMV retinitis who discontinue maintenance therapy should undergo regular eye examinations—optimally every 3 months—for early detection of relapse IRU, and then annually after immune reconstitution .</p> <p>IRU may develop in the setting of immune reconstitution.</p> <p>Treatment of IRU Periocular corticosteroid or short courses of systemic steroid.</p> <p>Initial therapy in patients with CMV retinitis, esophagitis, colitis, and pneumonitis should include initiation or optimization of ART.</p>

Table 53.5 Treatment of AIDS-Associated Opportunistic Infections (Continued)

Opportunistic Infection	Preferred Therapy	Alternative Therapy	Other Comments
Herpes simplex virus (HSV) disease	<p><i>Oral Lesions (for 5-10 days):</i> Valacyclovir 1 g PO bid or Famciclovir 500 mg PO bid or Acyclovir 400 mg PO tid</p> <p><i>Initial or Recurrent Genital HSV (for 5-14 days):</i> Valacyclovir 1 g PO bid, or Famciclovir 500 mg PO bid, or Acyclovir 400 mg PO tid</p> <p><i>Severe Mucocutaneous HSV:</i> Initial therapy acyclovir 5 mg/kg IV q8h After lesions begin to regress, change to PO therapy as above. Continue until lesions are completely healed.</p> <p><i>Chronic Suppressive Therapy for patients with severe recurrences of genital herpes or patients who want to minimize frequency of recurrences:</i> Valacyclovir 500 mg PO bid Famciclovir 500 mg PO bid Acyclovir 400 mg PO bid Continue indefinitely regardless of CD4 cell count.</p>	<p><i>For Acyclovir-Resistant HSV Preferred Therapy:</i> Foscarnet 80-120 mg/kg/day IV in 2-3 divided doses until clinical response</p> <p><i>Alternative Therapy</i> IV cidofovir (dosage as in CMV retinitis), or Topical trifluridine, or Topical cidofovir, or Topical imiquimod</p> <p><i>Duration of Therapy:</i> 21-28 days or longer</p>	<p>Patients with HSV infections can be treated with episodic therapy when symptomatic lesions occur, or with daily suppressive therapy to prevent recurrences.</p> <p>Topical formulations of trifluridine and cidofovir are not commercially available.</p> <p>Extemporaneous compounding of topical products can be prepared using trifluridine ophthalmic solution and the IV formulation of cidofovir.</p>

<p>Varicella-zoster virus (VZV) disease</p>	<p><i>Primary Varicella Infection (Chickenpox):</i> <i>Uncomplicated Cases (for 5-7 days):</i> Valacyclovir 1 g PO tid or Famciclovir 500 mg PO tid <i>Severe or Complicated Cases:</i> Acyclovir 10-15 mg/kg IV q8h for 7-10 days May switch to oral valacyclovir, famciclovir, or acyclovir after defervescence if no evidence of visceral involvement <i>Herpes Zoster (Shingles) Acute Localized Dermatomal:</i> For 7-10 days; consider longer duration if lesions are slow to resolve Valacyclovir 1 g PO tid or Famciclovir 500 mg tid <i>Extensive Cutaneous Lesion or Visceral Involvement:</i> Acyclovir 10-15 mg/kg IV q8h until clinical improvement is evident May switch to PO therapy (valacyclovir, famciclovir, or acyclovir) after clinical improvement (i.e., when no new vesicle formation or improvement of signs and symptoms of visceral VZV), to complete a 10-14 day course <i>Progressive Outer Retinal Necrosis (PORN):</i> Ganciclovir 5 mg/kg + foscarnet 90 mg/kg IV q12h + ganciclovir 2 mg/0.05 mL ± foscarnet 1.2 mg/0.05 mL intravitreal injection biw or Initiate or optimize ART <i>Acute Retinal Necrosis (ARN):</i> Acyclovir 10 mg/kg IV q8h for 10-14 days, followed by valacyclovir 1 g PO tid for 6 weeks</p>	<p><i>Primary Varicella Infection (Chickenpox) Uncomplicated Cases (for 5-7 days):</i> Acyclovir 800 mg PO 5 times/day <i>Herpes Zoster (Shingles) Acute Localized Dermatomal:</i> For 7-10 days; consider longer duration if lesions are slow to resolve Acyclovir 800 mg PO 5 times/day</p>	<p>In managing VZV retinitis: Consultation with an ophthalmologist experienced in management of VZV retinitis is strongly recommended. Duration of therapy for VZV retinitis is not well defined, and should be determined based on clinical, virologic, immunologic, and ophthalmologic responses. Optimization of ART is recommended for serious and difficult-to-treat VZV infections (e.g., retinitis, encephalitis).</p>

Table 53.5 Treatment of AIDS-Associated Opportunistic Infections (Continued)

Opportunistic Infection	Preferred Therapy	Alternative Therapy	Other Comments
Progressive multifocal leukoencephalopathy (PML) (JC virus infections)	There is no specific antiviral therapy for JC virus infection. The main treatment approach is to reverse the immunosuppression caused by HIV. Initiate ART immediately in ART-naïve patients Optimize ART in patients who develop PML in phase of HIV viremia on ART	None.	Corticosteroids may be used for PML-IRIS characterized by contrast enhancement, edema or mass effect, and with clinical deterioration.
<p>ACTG, AIDS Clinical Trials Group; ART, antiretroviral therapy; ARV, antiretroviral; ATV/r, ritonavir-boosted atazanavir; bid, twice a day; biw, twice weekly; BOC, boceprevir; CD4, CD4 T lymphocyte cell; CDC, The Centers for Disease Control and Prevention; CFU, colony-forming unit; CNS, central nervous system; CSF, cerebrospinal fluid; CYP3A4, cytochrome P-450 3A4; ddl, didanosine; DOT, directly observed therapy; DS, double strength; EFV, efavirenz; EMB, ethambutol; G6PD, glucose-6-phosphate dehydrogenase; GI, gastrointestinal; ICP, intracranial pressure; ICU, intensive care unit; IM, intramuscular; IND, investigational new drug; INH, isoniazid; IRIS, immune reconstitution inflammatory syndrome; IV, intravenous; LP, lumbar puncture; mm Hg, millimeters of mercury; NNRTI, non-nucleoside reverse transcriptase inhibitor; NRTI, nucleoside reverse transcriptase inhibitor; NSAID, nonsteroidal anti-inflammatory drugs; PegIFN, pegylated interferon; PI, protease inhibitor; PO, oral; PORN, progressive outer retinal necrosis; PZA, pyrazinamide; qAM, every morning; qid, four times a day; q(n)h, every "n" hours; qPM, every evening; RBV, ribavirin; RFB, rifabutin; RIF, rifampin; SQ, subcutaneous; SS, single strength; tid, three times daily; tiw, three times weekly; TVR, telaprevir; TMP-SMX, trimethoprim-sulfamethoxazole; ZDV, zidovudine.</p> <p><i>Quality of Evidence for the Recommendation:</i></p> <p>I: One or more randomized trials with clinical outcomes and/or validated laboratory endpoints II: One or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes III: Expert opinion</p>			

Blastomyces, and *Coccidioides* as causes of pneumonia depends on the geographic exposure of the patient. Among these mycoses, antigen detection techniques can be useful for finding *Cryptococcus* and *Histoplasma* organisms.

Therapy of opportunistic infections is summarized in Table 53.5.⁷⁴ While awaiting a specific diagnosis, it is reasonable to initiate empiric therapy in patients ill enough to merit admission to an ICU. For patients with a CD4⁺ T lymphocyte count greater than 250 to 300 cells/ μ L, levofloxacin or moxifloxacin and ceftriaxone or azithromycin and ampicillin-sulbactam would be reasonable choices. For patients with CD4⁺ T lymphocyte counts below 200 to 250 cells/ μ L, levofloxacin or moxifloxacin plus trimethoprim-sulfamethoxazole or pentamidine plus levofloxacin or moxifloxacin would be potential regimens.

If PCP is documented, trimethoprim-sulfamethoxazole is always the drug of choice in patients who can tolerate it. Table 53.5 lists alternatives for sulfa-intolerant individuals. Regardless of which specific anti-*Pneumocystis* regimen is used, corticosteroid therapy is indicated for any patient who presents with an oxygen pressure (Po₂) below 70 mm Hg or an alveolar-arterial gradient higher than 30 mm Hg.⁸⁶⁻⁸⁸ Patients with an initial Po₂ lower than 70 mm Hg are the subgroup with substantial mortality risk for whom corticosteroids have been shown to provide a survival benefit. Corticosteroids also provide more rapid resolution of pulmonary manifestations in patients who present with better pulmonary function, but survival in this population is so high that clinical trials have not been able to show survival benefit and thus corticosteroids are not conventionally recommended for patients who present with a room air Po₂ greater than 70 mm Hg. Some experts are concerned that corticosteroid use will be associated with reactivation of latent infections such as CMV or tuberculosis. However, reactivation of life-threatening infections has not been associated with this corticosteroid regimen.

How should a patient with AIDS-associated PCP be managed if there is no improvement, or if there is deterioration, after 5 to 10 days of therapy? The median time to improvement in clinical variables is 4 to 8 days; therefore, changes in therapy are probably not warranted before 5 to 10 days. At that point the accuracy of the diagnosis should be reassessed. Consideration should be given to repeat bronchoscopy with bronchoalveolar lavage or, perhaps, transbronchial biopsy to determine if CMV, fungi, mycobacteria, or a nosocomial bacterial process is present. Noninfectious processes such as congestive heart failure or tumor (e.g., Kaposi sarcoma) must also be considered. If pneumocystosis is the only causative process that can be identified, corticosteroids should be added to the regimen if they have not been already. Whether switching from one anti-*Pneumocystis* agent to another or whether adding a second agent is helpful has not been determined by clinical trials. Some human pneumocystosis isolates carry resistance mutations to sulfonamides, but such testing is available only in a few research centers, and the clinical significance of these mutations is unknown. Most experts add parenteral pentamidine to trimethoprim-sulfamethoxazole. Parenteral clindamycin-primaquine could be used as salvage regimens as well. Patients who have not improved after 14 to 21 days of therapy with specific chemotherapy plus corticosteroids have an exceedingly poor prognosis.

Should patients with AIDS-related PCP be intubated and provided with mechanical ventilation? The mortality rate for such patient populations was 70% to 80% in several series in the early 1980s.^{89,90} Since that era, supportive care has improved, and treatment modalities for concurrent infectious and noninfectious processes have become more effective. Patient selection for ventilatory support is probably also improving. Patients who have multiple active opportunistic infections, substantial weight loss, and no response to 14 days of therapy have a worse prognosis than previously ambulatory patients who develop respiratory failure during the first few days of therapy. Thus decisions about ICU support for patients with HIV infection and respiratory failure need to be individualized on the basis of a realistic assessment of prognosis, the availability of resources, and the preference of the individual patient.

As indicated earlier, the ICU is not an ideal setting for initiating antiretroviral therapy. It should be noted, however, that for PCP, early initiation of antiretroviral therapy is generally associated with increased survival and thus therapy generally should not be delayed.⁷³ However, the studies that have been done had very few patients with life-threatening manifestations of their acute opportunistic infection. Thus, for patients ill enough to be in the ICU, the initiation of antiretroviral therapy might be associated with an immune reconstitution syndrome that could make respiratory support difficult or impossible. Moreover, patients in the ICU may not be able to absorb oral antiretroviral therapy, or might have complicated drug interactions with other necessary drugs. Thus, decisions to start antiretroviral therapy in the ICU require considerable thought and do not lend themselves to simple algorithms.

CENTRAL NERVOUS SYSTEM DYSFUNCTION

Meningitis

In HIV-infected patients with CD4⁺ counts greater than 200 cells/ μ L, the causes of meningitis do not differ markedly from those in the normal population: *S. pneumoniae* and *Neisseria meningitidis* are the most common causes. For patients with CD4⁺ counts lower than 100 cells/ μ L, *Cryptococcus neoformans* is common.⁹¹

A diagnosis of cryptococcal meningitis is typically established by lumbar puncture: essentially 100% of patients with HIV-related cryptococcal meningitis should have a positive cerebrospinal fluid (CSF) cryptococcal antigen and CSF culture. Most patients will have an elevated CSF protein, low glucose, and elevated mononuclear cell count. Most will also have a positive serum cryptococcal antigen.

The therapy of choice for cryptococcal meningitis is liposomal amphotericin B for at least 2 weeks, plus flucytosine. Fluconazole should not be used for initial therapy, although it can be used after the initial 2 weeks if patients have a good clinical response.⁹²

Some patients with cryptococcal meningitis have symptomatic elevations of CSF pressure. Such patients should have therapeutic lumbar punctures to remove enough CSF to reduce the pressure to 20 to 25 cm H₂O. Multiple lumbar punctures may be needed. If after multiple lumbar punctures the patient still have symptomatic elevation of CSF pressure greater than 20 to 25 cm H₂O, the insertion of a ventricular shunt should be considered, although there are

no specific guidelines regarding when to place such a shunt. Corticosteroids should not generally be used to treat elevated intracranial pressure in this situation.^{93,95}

FOCAL CENTRAL NERVOUS SYSTEM LESIONS

Patients with HIV infection and CD4 counts less than 100 cells/ μ L may present with focal motor lesions, altered mental status, or seizures. Although the differential diagnosis is extensive, the major considerations are toxoplasmosis and lymphoma.^{96,97}

Central nervous system (CNS) toxoplasmosis may present as one or multiple lesions that represent reactivation of latent disease. Lesions are characteristically enhancing in a ringlike pattern and typically occur in the basal ganglia, but many different radiologic presentations have been documented.

All patients with CNS toxoplasmosis are IgG seropositive for toxoplasmosis using sensitive assays. However, some laboratories use less sensitive assays and thus some patients may appear to be seronegative. If lumbar puncture can be performed, a PCR for toxoplasmosis is positive in about 50% of cases, although there is no standardization of these *Toxoplasma* PCRs, making results variable from laboratory to laboratory.⁹⁸ The standard practice for HIV-infected patients with CD4 counts less than 200 cells/ μ L is to undergo an empiric trial of oral sulfadiazine plus pyrimethamine plus leucovorin. Most patients who have toxoplasmosis will show clinical and radiologic improvement within 2 weeks. If such improvement has not been documented, and the diagnosis is in doubt, a needle biopsy of the intracranial lesion should be considered.⁹⁹⁻¹⁰¹

CNS lymphoma can present identically to CNS lymphoma. A negative serum IgG for toxoplasmosis, and a negative CSF toxoplasma PCR should suggest lymphoma.¹⁰² Most patients with CNS lymphoma will have a positive CSF PCR for EBV (Epstein-Barr virus), although this test is neither 100% sensitive nor 100% specific for lymphoma. Patients who are CSF EBV PCR negative or in whom the diagnosis is uncertain may require a brain biopsy to document the lymphoma.

Therapy for lymphoma is one of several chemotherapeutic regimens. Patients continue to have a poor prognosis, but benefit from immune reconstitution with antiretroviral therapy.

FOCAL WHITE MATTER LESIONS

In patients with HIV, JC virus encephalitis (also known as progressive multifocal encephalopathy) causes focal white matter lesions that are associated with progressive motor, sensory, and neurocognitive dysfunction.¹⁰³ A small fraction of patients can present with rapidly progressive cognitive decline.

The CT scan or MRI images of JC virus encephalitis are characteristic of this disease. Diagnosis is usually confirmed by CSF PCR for JC virus. There is no specific therapy. Patients may stabilize or improve if antiretroviral therapy results in immune reconstitution.¹⁰⁴

DIFFUSE ENCEPHALOPATHY

Patients with HIV infection can develop significant cognitive dysfunction due to nonfocal entities including HIV

encephalopathy and CMV encephalitis. HIV encephalitis characteristically progresses slowly and has ventricular enlargement and cerebral atrophy on brain imaging. The CSF is unremarkable, and there is no diagnostic CSF test.

CMV encephalitis, in contrast, is rapid in progression and has a neutrophilic pleocytosis in the CSF and a positive CSF PCR for CMV.^{105,106} Imaging shows either periventricular enhancement or focal nodules. Therapy is typically not successful in reversing the cerebral dysfunction. Either ganciclovir, foscarnet, or a combination of both drugs can be used in addition to the institution of antiretroviral therapy.

DIARRHEA

Patients with HIV infection and CD4 counts below 100 cells/ μ L can develop severe diarrhea due to a wide range of opportunistic pathogens including CMV, cryptosporidiosis, or enteric bacteria such as *Salmonella*, *Shigella*, or *Campylobacter*. Diarrhea in HIV-infected patients can be so severe that patients can have life-threatening malabsorption, electrolyte abnormalities, and bowel perforations. Patients need a thorough stool evaluation for common pathogens such as *Clostridium difficile*, which is the most common cause of diarrhea in this patient population, even though it is not an opportunistic pathogen. If stool cultures are negative, testing samples for ova and parasites might be indicated if there is a history compatible with exposure.

For patients with negative evaluation of multiple stool samples, a sigmoidoscopy with biopsy is indicated to assess the presence of CMV. CMV colitis occurs exclusively in patients with CD4⁺ T lymphocyte counts lower than 100 cells/ μ L. CMV colitis is best diagnosed by biopsy: there is no reliable correlation with serum CMV PCR or with stool culture or PCR for CMV. The therapy of choice for CMV colitis is intravenous ganciclovir. Intravenous foscarnet is also effective but is more toxic. Oral valganciclovir is not indicated for patients with severe diarrhea but can be used as maintenance therapy once the CMV colitis is controlled. The most effective remedy for CMV colitis is immune reconstitution with antiretroviral therapy. As soon as absorption seems likely, antiretroviral therapy should be initiated.

HYPOTENSION

Patients with HIV infection develop hypotension resulting from the same types of disorders as with non-HIV-infected individuals—sepsis from a primary infection or a wound or device (especially an intravascular access device), fluid depletion from vomiting or diarrhea, and hemorrhage from a gastrointestinal lesion are examples of common causes. The evaluation of hypotension in a patient with HIV infection must take into account factors particular to this patient population: HIV-infected patients are susceptible to opportunistic infections; they undergo many procedures that can be associated with infectious complications; and they receive an array of drugs, some of which have cardiovascular effects. Thus, evaluating hypotension in this patient population requires a comprehensive and thorough approach. A differential diagnosis of the major causes is shown in [Table 53.6](#). Adrenal function always deserves special attention

Table 53.6 Causes of Hypotension in Patients with HIV Infection

Process	Examples of Causes
Distributive Shock	
Septic shock	
Bacterial	Pneumococcal or <i>Haemophilus</i> pneumonia Vascular access infection Surgical wound
Viral	CMV infection, disseminated VZV infection
Fungal	<i>Histoplasma</i> , <i>Coccidioides</i> , <i>Cryptococcus</i> organisms Vascular access–related candidemia <i>Pneumocystis jiroveci</i> pneumonia
Adrenal insufficiency	Tuberculosis, fungal disease, CMV infection, HIV infection
Oligemic shock	
Dehydration	Bacterial diarrhea <i>C. difficile</i> diarrhea
Gastrointestinal hemorrhage	CMV colitis Gastrointestinal lymphoma
Cardiogenic Shock	
Cardiomyopathy	HIV infection
Endocarditis	Bacterial pathogens related to intravenous drug abuse
Extracardiac Obstruction	
Pericardial tamponade	Lymphoma, Kaposi sarcoma, primary effusion lymphoma Fungal infection, tuberculosis
Pericardial constriction	Tuberculosis, fungal infection
Massive pulmonary embolus	Inactivity, inanition
CMV, cytomegalovirus; HIV, human immunodeficiency virus; VZV, varicella-zoster virus.	

because several viral processes, fungal and mycobacterial diseases, HIV, and drugs can suppress the adrenal axis and either cause hypotension or exacerbate it.

PREVENTION OF OPPORTUNISTIC INFECTION

Intensivists usually focus on the management of acute processes, but if attention is not provided to opportunistic infection prevention, patients hospitalized for one process may develop a second life-threatening process given the high incidence of opportunistic infections.

Patients with HIV infection typically receive several antimicrobial agents to reduce the likelihood they will acquire opportunistic infections. *Primary prophylaxis* is the term used to indicate strategies that reduce the likelihood of an initial episode of a disease process. *Secondary prophylaxis* is the term used to indicate strategies that prevent recurrences or relapses. *Chronic suppressive therapy* is identical to secondary prophylaxis: This refers to regimens that are continued after the initial therapeutic course to prevent relapses.

All patients with HIV infection and CD4⁺ T lymphocyte counts below 200 cells/ μ L typically receive anti-*Pneumocystis* prophylaxis. Trimethoprim-sulfamethoxazole is the regimen of choice. Patients who actually take this drug have very few breakthroughs of PCP and receive considerable protection against toxoplasmosis and certain routine bacterial infections. Alternative regimens include monthly dapsone, weekly dapsone-pyrimethamine, or daily aerosol pentamidine. Prophylaxis against *M. avium* complex is recommended for patients with CD4⁺ T lymphocyte counts under 100 cells/ μ L; clarithromycin and azithromycin are currently the drugs of choice.⁷⁴

Some clinicians also use fluconazole or acyclovir prophylaxis to reduce the frequency of fungal and viral processes, respectively, although this is not recommended because of issues of cost, pill burden, and the emergence of resistant pathogens. Isoniazid prophylaxis is important for any patient with a tuberculin skin test that shows more than 5 mm of induration or a history of substantial recent exposure.

HIV TRANSMISSION IN THE INTENSIVE CARE UNIT

Transmission of HIV is an issue that requires attention in the ICU.¹⁰⁷⁻¹⁰⁹ No evidence exists that HIV-infected health care professionals can infect patients, regardless of what procedure they perform, with the exception of two unusual and unexplained events. Intensivists should realize that although there are no federal policies defining how HIV-infected practitioners should be credentialed and monitored, many hospitals have policies and procedures. Some are modeled after guidelines from the Society of Healthcare Epidemiology.^{108,110}

HIV patients pose a risk to health care professionals.¹⁰⁷⁻¹¹⁰ This risk can be substantially reduced by staff education, by strict monitoring for compliance with universal precautions, and by having proper equipment. Almost all HIV transmission has occurred in an occupational setting as a result of injuries involving sharp instruments (e.g., needles, scalpels). The risk of such injuries is about one case of HIV transmission per 250 injuries, but the likelihood of transmission in an individual accident depends on the amount of viremia at the time of the accident (late-stage patients generally have more circulating virus than do early-stage patients) and the nature of the accident. Most authorities recommend immediate prophylaxis if a significant injury occurs involving an HIV-infected patient. Considerable debate exists over the optimal choice of drugs and the optimal duration of therapy, but it is clear that initiating therapy within a period of hours rather than days is best. Many authorities now advocate an antiretroviral regimen for any situation when the patient and health care provider determine that therapy is appropriate, and continue that for 4 to 6 weeks. If providers have questions about appropriate medical treatment for occupational exposures, 24-hour assistance is available from the Clinicians' Post Exposure Prophylaxis Hotline (PEpline) at 1-888-448-4911 (<http://www.ncccs.ucsf.edu>).¹¹¹

Since surveillance of injuries began, 57 documented cases of occupational transmission of HIV infection have occurred, and 138 possible cases have been documented. More cases involve nurses or phlebotomists than physicians.

No transmission in the operating suite has been documented. There have been no documented cases of transmission for over a decade.

HUMAN STEM CELL, BONE MARROW, AND SOLID ORGAN TRANSPLANT RECIPIENTS

Solid organ transplant recipients and human stem cell recipients have much in common in terms of life-threatening complications that bring them to the ICU. Each of these populations is immunosuppressed and susceptible to opportunistic infections. Each of these populations receives immunosuppressive drugs that have direct toxicities and that may cause clinically important drug interactions with other medications.

Although these patient groups have much in common, they also have many profound differences. Their degrees of immunosuppression are very different: kidney transplant recipients, for example, do not have the same magnitude of risk for opportunistic infection as liver transplant recipients or human stem cell transplant recipients. The time period of severe immunosuppression differs with each patient group. Last, the specific organ being transplanted has an obvious major impact on the complications likely to be encountered: a transplanted liver must be dealt with much differently than a transplanted lung or transplanted stem cells in terms of the infectious and noninfectious complications that are likely to occur.

The field of transplantation is also evolving rapidly. The supportive care in ICUs has evolved over the past decade. Similarly, the immunosuppressive regimens and the prophylactic and therapeutic regimens employed to prevent and treat complications have changed dramatically, rendering some older timelines and guidelines less relevant in the current era.

Timelines are useful to provide clinicians with a general understanding of when infectious and noninfectious complications occur after a transplant procedure. [Figure 53.6](#) demonstrates the typical return of cells and cell function after a stem cell transplant. [Figures 53.7](#) and [53.8](#) demonstrate timelines typical for stem cell and solid organ transplant infections. However, the occurrence of complications will vary depending on the details of transplant management that may be unique to an institution or a specific protocol, so that these figures should not be considered as inviolable.

The following general principles are useful to keep in mind when approaching transplant recipients, in addition to the principles listed at the beginning of the chapter:

- The risk of infection is related to the “net state of immunosuppression,” which is related to the function of the patient’s pretransplant immune status, conditioning regimens, antirejection chemotherapy, as well as severity of illness and nutritional status. Net immunosuppression cannot be measured easily: it involves the number and function of neutrophils, T lymphocytes, and B lymphocytes. Although neutrophil number is a highly reliable surrogate for susceptibility to bacterial diseases, measures of cellular immune function, which are relevant to many viral and fungal pathogens, are not reliable surrogates in terms of sensitivity or specificity for predicting disease.

Thus, susceptibility to viral and fungal pathogens is more difficult to predict.

- The risk of noninfectious complications is dependent on the organ transplanted and the immunosuppressive regimen used.
- Distinguishing infectious from noninfectious complications can be challenging, emphasizing the need for a broad consideration of causes of fever, hypotension, or organ-related syndromes, and the institution of prompt diagnostic tests that focus on both infectious and noninfectious causes.
- With solid organ transplants or stem cell transplants, the donor is a source of infection if the donor had an unrecognized transmissible infection at the time of organ donation, or if the donor had a latent infection that was transmitted with the donated organ.
- With solid organ transplants, complications of the surgical procedure must be considered when postoperative complications occur.
- Organ transplant recipients characteristically have extensive contact with health care environments and may have been receiving antimicrobial prophylaxis: these factors influence the spectrum of likely causative organisms.
- Diagnostic studies for infections rely more and more on molecular testing, although tissue biopsy and cultures of blood and suspicious body fluids and anatomic areas remain important. Tissue biopsies can be especially useful for differentiating infectious and noninfectious causes.
- Drug levels and microbial markers of infection must be carefully monitored to enhance the likelihood of effective therapy and minimize the likelihood of drug-related toxicities.

DIAGNOSTIC APPROACH

The management of organ transplant recipients focuses on algorithmic monitoring of neutrophil and lymphocyte number, organ function, drug levels, prophylactic drugs, and microbiologic parameters. Most patients will be managed by standard practice protocols that routinely order tests at intervals appropriate for the time period after transplant and for the patient’s clinical status.

Programs often have specific targets for drug levels for immunosuppressive drugs. Given the drug interactions that occur in the ICU due to polypharmacy, and other factors altering pharmacokinetics, drugs levels must be monitored closely.

INFECTIOUS COMPLICATIONS OF TRANSPLANTATION

Cytomegalovirus

CMV is one of the most prominent pathogens for solid organ and stem cell transplant recipients. In urban areas of the United States, 60% to 70% of the population is seropositive for CMV, and thus either or both donor and recipient may have latent CMV infection at the time of the transplant procedure. In these populations, transplants from CMV-positive donors to CMV-negative recipients carry particular risk for reactivation of CMV disease in the organ recipient. In addition, any CMV-positive recipient is at risk for CMV disease during the period of immunosuppression.

CMV seronegative patients may acquire primary CMV infection from a CMV-infected organ. Acquisition from CMV-infected blood or blood products is becoming less and less likely since blood products have been screened or filtered.

Laboratory monitoring of patients for evidence of CMV disease using a DNA amplification assay is an important feature in efforts to reduce morbidity and mortality rates resulting from CMV. (CMV antigen detection in buffy coat smears is used less and less commonly and cannot be used in neutropenic patients.) Intensivists need to understand how to interpret these assays in terms of starting empiric, preemptive, or definitive therapy even though the assays are not standardized nor have they been studied in many adequately powered trials.

A seroconversion of a serum PCR test for CMV is usually an indication to treat CMV preemptively or therapeutically in most organ transplant recipients. Some programs make distinctions between low and high positive values based on copy number, and some require more than one consecutive low copy positive to be considered an indication for therapy: each institution has its own approach based on its own experience or the experience of a group with a convincing record for successful outcome.

Serial monitoring of CMV PCR or buffy coat antigen permits the use of preemptive therapy, that is, the use of CMV therapy at a time when there is laboratory evidence of infection but no clinical evidence of disease.

CMV disease in these populations may occur with serologic evidence of CMV infection (i.e., colitis or pneumonitis may occur when the serum CMV PCR is negative). Thus, treatment should be started either preemptively or when there is histologic or cytologic evidence of disease.

CMV disease can cause substantial morbidity and mortality risks including fever, hypotension, pneumonitis, hepatitis, glomerulitis, enteritis, and allograft injury. The availability of ganciclovir, foscarnet, and cidofovir has enabled these conditions to be treated successfully in many instances, although all three of these drugs are associated with substantial toxicity. Ganciclovir is the drug which has been studied most extensively. However, its toxicity on bone marrow, and especially on neutrophil counts, makes this an undesirable drug for many stem cell transplant programs.

Whether immune globulin (either immune globulin or specific hyperimmune globulin) adds anything to the potency of therapeutic regimens is not clear, although some programs administer these products when they are available.

Pneumocystis Pneumonia

PCP has been reported in recipients of most types of organ transplants. Most organ transplant programs use PCP prophylaxis during the period of perceived susceptibility, although there can be underappreciation of the duration of true risk, leading to premature discontinuation of prophylaxis.^{30,112} Trimethoprim-sulfamethoxazole is usually the prophylactic agent of choice because it is more effective than other agents, is well tolerated, and reduces the frequency of urinary tract infections and other potential complications (e.g., disease resulting from *Nocardia*, *S. pneumoniae*, and *Haemophilus* organisms). However,

trimethoprim-sulfamethoxazole is moderately immunosuppressive, and thus some human stem cell transplant programs prefer aerosolized pentamidine or oral atovaquone for prophylaxis.

As noted for other patient populations, diagnosis of PCP is usually based on demonstration of organisms by immunofluorescence in sputum or bronchoalveolar lavage. There is no reliable serologic test for PCP. Lung biopsy is rarely necessary to document PCP given the sensitivity of bronchoalveolar lavage and immunofluorescent staining at most medical centers.

The therapy of choice is trimethoprim-sulfamethoxazole, even if the patient was on trimethoprim-sulfamethoxazole prophylaxis at the time that acute disease developed. Intravenous pentamidine or oral primaquine combined with intravenous clindamycin are alternative therapies. It is logical to use corticosteroids for patients with moderate or severe PCP, as adjunct therapy, but the literature supporting this recommendation is not nearly as robust as the literature supporting the use of corticosteroids for HIV-associated PCP.

Fungal Infections

The spectrum of causative fungal organisms is changing because of changes in antifungal prophylactic regimens.^{113,114}

With the use of fluconazole prophylaxis, *Candida albicans* infections became less common and molds, especially *Aspergillus*, became more important pathogens, as did fluconazole-resistant *Candida*. Some programs are now using voriconazole prophylaxis, which has resulted in the development of disease due to voriconazole-resistant molds such as *Mucor* and certain non-*albicans Candida*. Thus, clinicians must know which antifungal prophylaxis has been used in order to anticipate which complications will occur.

Candida infections have traditionally been a major threat to transplant recipients. Mucosal candidiasis is a common complication. Esophageal candidiasis can lead to bloodstream infections as can *Candida* invasion of ulcerated bowel or perhaps intact bowel in neutropenic patients. Hepatosplenic candidiasis can be a cause of prolonged fever and systemic sepsis which is difficult to diagnose without CT or MRI of the liver and spleen and biopsy of suspicious lesions. Catheter-related *Candida* sepsis has also been a well-documented complication of transplantation.

Diagnosis of *Candida* requires culture of blood or the affected organ or a tissue biopsy. Serologic assays based on β -glucan detection are popular. However, these tests are not highly sensitive or specific, and there is considerable variability in assay performance from specimen to specimen and laboratory to laboratory.

The widespread use of azole prophylaxis has reduced the frequency of *Candida albicans* disease. Azole-resistant *Candida*, such as *Candida krusei* or *Candida glabrata*, are replacing *C. albicans* as pathogens.

The therapy of choice for *Candida* disease depends on the species of *Candida* recovered and its drug susceptibility. Echinocandins are active against almost all *Candida* species, as is amphotericin B. Azoles are not ideal initial choices in the ICU because of the risk to the patient if the causative *Candida* is azole sensitive. Most laboratories will perform azole susceptibility testing for *C. albicans*, and perhaps for other species.

Mold infections are becoming increasingly prominent causes of posttransplant morbidity because of the high degree of immunosuppression that many patients are exposed to, and because of the use of azole antifungal prophylaxis, which prevents most *Candida* infections but is not active against all molds such as certain species of *Aspergillus*, *Mucor*, and *Fusarium*.

Mold infections are best documented by tissue biopsy, although such biopsies are not always feasible due to the anatomic location of the suspicious lesion, the severity of patient illness, or the presence of a severe coagulopathy. Serologic tests are not yet highly sensitive and specific. Although some clinicians are enthusiastic about using the galactomannan test in the bronchoalveolar lavage or blood, this test is not optimally sensitive for molds, especially when used on serum.¹¹⁵⁻¹¹⁸ Many clinicians are less enthusiastic about the serum β -glucan test, which was popular as a test for fungal disease, but which is increasingly seen as insensitive, nonspecific, and subject to laboratory variation.^{63,119-123}

Respiratory Viruses Including Respiratory Syncytial Virus

Diffuse pulmonary infiltrates in any patient population may be caused by respiratory viruses. It is especially important to identify the presence of respiratory viruses because they are transmissible to other patients, hospital staff, and families. Most respiratory viruses are not true opportunistic pathogens, and thus, there is little evidence that they occur more frequently or cause more severe disease in transplant recipients than in immunocompetent patients. Transplant recipients may shed influenza, RSV, adenovirus, or coronavirus, for example, for longer periods of time following acute infection than immunocompetent patients, but their pulmonary disease is not necessarily more severe or more prolonged.

RSV is one respiratory virus that is opportunistic, however, in stem cell transplant recipients. Although RSV can, like other community-acquired viruses, cause disease in any patient population, it is especially lethal in those with stem cell transplants. Thus, RSV must be specifically sought in this patient population, as well as their visitors and health care providers, so that it does not spread to highly susceptible patients. RSV is best diagnosed by nasopharyngeal washes and molecular testing or by molecular testing of bronchoalveolar lavage.¹²⁴⁻¹²⁶

Many clinicians treat RSV pneumonia in transplant recipients with aerosolized ribavirin, monoclonal antibody against RSV, or both, but the efficacy of these regimens is controversial.^{127,128}

NONINFECTIOUS COMPLICATIONS IN HUMAN STEM CELL TRANSPLANT RECIPIENTS

Graft-Versus-Host Disease

For human stem cell transplant recipients, the effects of the graft-attacking host cells rather than just the tumor can cause clinically significant disease that may be mild, severe, or even life-threatening. Typical manifestations are rash ("skin graft-versus-host disease") and diarrhea ("gut graft-versus-host disease"). These manifestations are difficult to

distinguish from other causes of rash or diarrhea without tissue biopsy. It is important to make a specific diagnosis, however, because the treatment of graft-versus-host disease is to increase immunosuppression. If the diarrhea is caused by an infectious agent such as CMV, or the rash is due to disseminated herpes simplex, the appropriate treatment would be the opposite (i.e., reduction in immunosuppression in conjunction with specific therapy against the pathogen).

Immune Reconstitution Syndrome

For human stem cell transplant recipients, stem cell engraftment and return of neutrophils may be accompanied by inflammatory syndromes that can mimic infectious diseases. This syndrome is usually defined by a return of circulating neutrophil count in conjunction with exacerbation of inflammation at a new or preexistent site of infection or inflammation. There is no specific diagnostic test for this syndrome: it is a diagnosis of exclusion, and infectious causes must be carefully sought.

Toxicities of Immunosuppressive Drugs

Diagnosis and therapy of opportunistic infections and nosocomial infections should follow the guidelines given in Chapters 51 to 53 and 55. In choosing therapies, attention must be focused on the toxicities of antimicrobial agents and how they influence the outcome of the transplanted organ. In addition, drug interactions are important, especially with cyclosporine. Drugs that alter hepatic metabolism, such as rifampin, rifabutin, and fluconazole, can have substantial influence on cyclosporine levels and thus need to be used with careful pharmacologic attention. Finally, clinicians must recognize that new immunosuppressive regimens and changing prophylactic regimens are changing the spectrum of infectious complications. As mentioned earlier, fungal infections are increasingly likely to be caused by species other than *C. albicans*: non-*albicans Candida*, *Fusarium*, and *Rhizopus* are recognized with increasing frequency. Similarly, prophylaxis with valganciclovir is reducing CMV disease and pushing disease that does occur later and later in relation to the transplant procedure. Viruses such as HHV-6 and BK virus are causing disease. Thus, clinicians need to look for a changing spectrum of pathogens, as well as changing manifestations if the morbidity and death caused by infection are to be managed optimally.

KEY POINTS

- Knowledge of a patient's specific defects in immunologic and inflammatory response helps predict which opportunistic pathogens are most likely to occur.
- ICUs are increasingly successful in enabling immunosuppressed patients to survive acute crises, especially if the defect in immunologic or inflammatory function is reversible over time or by replacement therapy.

KEY POINTS (Continued)

- For neutropenic patients, gram-positive cocci have become more frequent than gram-negative bacilli as causes of life-threatening illness.
- Resistance to antimicrobial agents is becoming a major problem including bacteria (e.g., carbapenase-producing Enterobacteriaceae, MRSA, vancomycin-resistant enterococci, and penicillin-resistant pneumococci) and fungi (e.g., fluconazole-resistant *Candida* organisms) as well as PCP, and viruses (e.g., acyclovir-resistant herpes simplex and ganciclovir-resistant CMV).
- In neutropenic patients, broad-spectrum empiric therapy should be considered when treating any febrile process, with reduction in antimicrobial drugs once the severity of the illness and the causative process are better defined.
- A substantial fraction of HIV-infected patients with PCP-related respiratory failure can survive mechanical support and be discharged from the hospital.
- Adjunctive corticosteroid therapy is indicated for respiratory failure related to PCP.
- Organ transplant recipients develop opportunistic infections at relatively predictable points depending on the type of transplantation and the specific immunosuppressive regimen used.

Specific Infections with Critical Care Implications

Henry S. Fraimow | Annette C. Reboli

CHAPTER OUTLINE

OVERWHELMING INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

Acute Bacterial Meningitis

Encephalitis

Brain Abscess

Spinal Epidural Abscess

FULMINANT ENDOVASCULAR INFECTIONS

Acute Infective Endocarditis

Device-Related Endovascular Infections

PRIMARY BACTEREMIAS

Meningococcemia and Meningococcal Sepsis

Primary Pneumococcal Bacteremia

Staphylococcus aureus Bacteremia

TOXIN-MEDIATED INFECTIONS

Staphylococcal Toxic Shock Syndrome

Streptococcal Toxic Shock Syndrome

Clostridial Toxic Shock Syndrome

Tetanus

Botulism

Diphtheria

SERIOUS SKIN AND SKIN STRUCTURE INFECTIONS

Necrotizing Fasciitis

Clostridial Myonecrosis (Gas Gangrene)

Vibrio Infections

Community-Acquired MRSA

SERIOUS GASTROINTESTINAL AND INTRA-ABDOMINAL INFECTIONS

Bacteremia Associated with Diarrheal Illness

Peritonitis

Intra-abdominal Abscess

Biliary Tract Infections

Pancreatic Infections

Clostridium difficile Colitis

LIFE-THREATENING INFECTIONS OF THE HEAD AND NECK

Ludwig's Angina, Lateral Pharyngeal Space Infections, and Peritonsillar Abscess

Lemierre Syndrome

Epiglottitis

Mediastinitis

SERIOUS VECTOR-BORNE INFECTIONS

Rocky Mountain Spotted Fever

Ehrlichiosis and Anaplasmosis

Malaria

Dengue

SEVERE VIRAL INFECTIONS

Hantavirus Pulmonary Syndrome

Influenza

POTENTIAL AGENTS OF BIOTERRORISM

Anthrax

Smallpox

Plague

Tularemia

Viral Hemorrhagic Fevers

Infections and their complications, including severe sepsis and septic shock, are major indications for admission to critical care units worldwide. An enormous variety of infections can result in critical illness, and review of all of these syndromes is beyond the scope of this chapter. The diseases discussed here include the most common infectious syndromes likely to be encountered by critical care specialists, as well as less common infections of particular epidemiologic importance or those conditions in which critical care management is an essential component of management. The topics of community-acquired pneumonia, urinary

tract infections, and nosocomial infections including device-associated infections are addressed specifically in other chapters.

OVERWHELMING INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

Most patients with serious central nervous system (CNS) infections will require either admission to an intensive care unit (ICU) or the participation of a critical care specialist

in their management. This is because of the severity of these infections at the time of presentation, the need for rapid initiation of diagnostic and therapeutic interventions to optimize outcomes, and the potential for rapid progression with development of fulminant and devastating complications. The major acute CNS infectious syndromes include bacterial meningitis, encephalitis, brain abscess, and spinal epidural abscess, although other primary and secondary infectious syndromes can present catastrophically, such as nonbacterial infectious meningitis, suppurative intracranial thrombophlebitis, and mycotic aneurysms. The presentations of all of these infectious syndromes may overlap, and they may also mimic the presentations of noninfectious CNS catastrophes such as stroke or hemorrhage.

ACUTE BACTERIAL MENINGITIS

EPIDEMIOLOGY, PATHOGENESIS, RISK FACTORS, AND CLINICAL PRESENTATION

The annual incidence of bacterial meningitis in individuals older than 16 years of age in developed countries has been steadily decreasing and was estimated at less than 2 cases per 100,000 in the United States in 2006-2007.^{1,3} In recent studies from the United States and the Netherlands, the predominant organisms in microbiologically confirmed cases of bacterial meningitis in adolescents and adults were *Streptococcus pneumoniae* (45-60%), *Neisseria meningitidis* (15-30%), *Haemophilus influenzae* (7%), and *Listeria monocytogenes* (5%),^{2,4} with no pathogen identified in approximately 10% of cases.^{1,2} *Streptococcus agalactiae* (group B β -hemolytic streptococcus) has also recently emerged as an important cause of meningitis in adults, causing over 5% of cases of microbiologically defined episodes in the United States from 1998 to 2007. In some studies, rates of culture-negative cases were as high as 25%.⁵ Important recent changes in microbiologic causes of bacterial meningitis reflect the impact of current vaccination strategies. These changes include the marked reduction in cases of *H. influenzae* meningitis in both children and adults, and the introduction of the conjugated pediatric pneumococcal vaccine that has resulted in decreased rates of invasive childhood pneumococcal disease in children and adults.^{3,6} A new meningococcal vaccine, which has the potential to diminish the rates of meningococcal disease in high-risk populations, has also been approved for use in adolescents and high-risk adult populations.⁷ Another important trend is the increase in prevalence of nosocomial meningitis.⁴ The microbiology of nosocomial meningitis differs from that of community-acquired cases, including higher rates of staphylococcal infection and infection due to a variety of aerobic gram-negative organisms.

The major route of acquisition of bacterial meningitis follows colonization of the nasopharynx with subsequent hematogenous spread and invasion of cerebrospinal fluid (CSF). Less frequently, infection occurs from hematogenous dissemination from distant sites or from other localized intracranial focal infections including sinusitis, mastoiditis, or otitis, or it is secondary to trauma or neurosurgery. In addition to trauma and contiguous focal infectious processes facilitating invasion of the CSF by bacteria, there is a wide variety of immunologic deficits that result in impaired clearance of encapsulated organisms. These

include organism-specific deficits such as terminal complement deficiencies predisposing to meningococcal disease, as well as more general deficits such as immunoglobulin deficiencies, splenectomy, alcoholism, cirrhosis, diabetes mellitus, and human immunodeficiency virus (HIV) infection.^{2,4} Patients with defects leading to impaired cell-mediated immunity including advanced age and general debility, as well as hematologic malignancies, chemotherapy, and use of tumor necrosis factor (TNF)- β inhibitors, are predisposed to *Listeria* infection.⁸

The presenting symptoms of bacterial meningitis include fever, headache, stiff neck, and altered sensorium. In the recent large series of 696 cases from the Netherlands, 95% had at least two of these four symptoms, although only 44% had all of the classic triad of headache, fever, and stiff neck.² Other important presenting symptoms in this cohort included nausea in 74%, focal neurologic deficits in one third of cases, and Glasgow Coma Score of less than 8 in 14% of cases.² Rash, especially a petechial or purpurral rash that may be an important clue for the diagnosis of meningococcal meningitis, was seen in 26%.² Presenting symptoms alone without CSF findings or microbiologic data cannot adequately distinguish between bacterial meningitis and viral or other aseptic meningitis. However, certain features are more suggestive of bacterial rather than viral origin including winter versus summer onset, rapid progression of disease, presentation in shock, and presence of another focal site of bacterial infection such as sinusitis, otitis, or pneumonia. In addition to viruses, other nonbacterial infections including cryptococcosis, tuberculous meningitis, rickettsial diseases, Lyme disease, and syphilis are in the differential diagnoses of acute bacterial meningitis.

DIAGNOSTIC STRATEGIES AND EARLY MANAGEMENT OF SUSPECTED BACTERIAL MENINGITIS

The early management of suspected bacterial meningitis requires careful coordination and appropriate sequencing of the procedures necessary for establishing the diagnosis (lumbar puncture and imaging studies) and the interventions necessary for optimal treatment (antibiotics and dexamethasone). Rapid initiation of therapy leads to improved outcomes but may decrease specific microbiologic yield on CSF analysis.^{1,5} Similarly, although lumbar puncture can usually be performed safely without any imaging studies, computed tomography (CT) scan may be required to minimize the risk of this procedure, leading to potential delays in institution of antimicrobial therapy.⁹ Recent reviews and published practice guidelines have tried to place these competing urgencies in perspective, using data culled from multiple recent prospective studies and randomized trials.^{1,5} One algorithm for early management of bacterial meningitis is shown in [Figure 54.1](#).

The primary tenet of these algorithms is that the initiation of treatment assumes highest priority and thus any delay in performing a lumbar puncture because of the need for imaging or because of other patient-specific contraindications should not delay the administration of antibiotic therapy. Brain herniation is a feared but rare complication of lumbar puncture when performed for diagnosis of suspected meningitis in patients with elevated intracranial pressure.¹⁰ One recent study of a cohort of 301 patients with

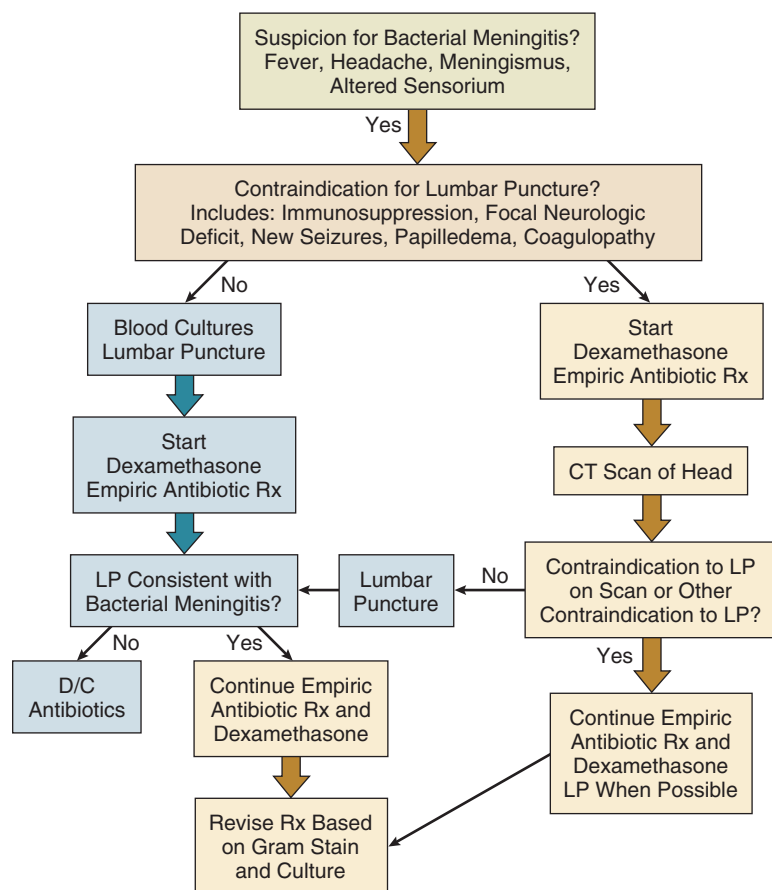

Figure 54.1 Algorithm for early management of suspected bacterial meningitis including determining when to suspect the diagnosis, when imaging should be performed prior to lumbar puncture, and when to initiate or discontinue empiric antibacterial therapy and adjuvant steroids. (Modified with permission from van de Beek D, de Gans J, Tunkel AR, et al: Community-acquired bacterial meningitis in adults. *N Engl J Med* 2006;354:44-53; and Tunkel AR, Hartman BJ, Kaplan SL, et al: Practice guidelines for the management of bacterial meningitis. *Clin Infect Dis* 2004;39:1267-1284.)

suspected bacterial meningitis described the relative safety of lumbar puncture without CT scanning in patients without specific clinical contraindications.⁹ Proposed criteria for performing imaging prior to lumbar puncture include new-onset seizures, prior CNS disease, immunocompromised state, papilledema, focal neurologic deficits, or moderate to severe impairment of consciousness.⁵ Only approximately 45% of patients with bacterial meningitis will have criteria for neuroimaging prior to lumbar puncture, although it remains standard practice in many hospitals for all patients with suspected meningitis to undergo imaging first.^{1,5} The main purpose of early imaging is to find evidence of brain shift and both noncontrast CT and magnetic resonance imaging (MRI) can be used for this purpose. Considerations for the optimal imaging modality may be different when imaging tests are done to manage subsequent complications of meningitis or to better define space-occupying lesions. Other specific contraindications to lumbar puncture include coagulopathies and presence of local processes overlying the lumbar puncture site such as stasis ulcers, burns, or cellulitis.

The diagnosis of bacterial meningitis relies heavily on analysis of CSF parameters including opening pressure, cell count, protein, glucose, and Gram stain and culture. Typically, patients with bacterial meningitis have elevated opening pressures of 200 to 500 mm H₂O, including 40% with opening pressure greater than 400 mm in one recent cohort.^{2,5} White blood cell (WBC) counts may range from 100 to 10,000 cells/mm³, most commonly in the 1000 to

5000 range; very low CSF WBC counts are associated with a worse prognosis.^{4,5} Usually there is a polymorphonuclear (PMN) cell predominance of 80% or greater, although up to 10% will have a lymphocytic predominance, particularly early on. CSF-to-serum glucose ratios are less than 0.4, and CSF protein levels are nearly always increased.⁵ In a study comparing cohorts of patients with bacterial and viral meningitis, CSF glucose ratios of less than 0.31, total WBC counts of greater than 2000, and total PMN cell counts of greater than 1180 have been predictive of bacterial rather than viral meningitis.¹¹ Other studies have suggested that protein values of greater than 0.5 g/L and WBC counts greater than 100 are also independently predictive of bacterial meningitis.¹² Gram stains are positive in 60% to 90% of cases of bacterial meningitis, and results on Gram stain are reported to be 97% specific as to cause.⁵ Yield of Gram stain is higher on specimens concentrated by Cytospin centrifuge. Highest diagnostic yield from Gram staining is for *S. pneumoniae* meningitis; Gram stains in *Listeria* meningitis are positive in only one third of cases because of the lower inoculum of bacteria in the CSF. Clinicians should also be aware that preliminary “stat” Gram stains done during off-hours are more likely to be misinterpreted; thus, stains should always be reviewed by trained clinical microbiologists before modifying therapy based on a Gram stain report. In untreated patients, cultures will ultimately be positive in up to 90% of cases. Initiation of antibiotic therapy prior to lumbar puncture will not significantly alter cell count, protein, glucose, and even Gram stain results but will decrease CSF culture

yield by up to 20%.^{5,12} Blood cultures should be performed in all patients with suspected bacterial meningitis prior to initiation of antibiotics, even if the lumbar puncture is delayed.

Additional CSF and blood tests have been used to confirm a diagnosis of bacterial meningitis or help distinguish bacterial from viral disease. Latex agglutination tests for bacterial antigens, although initially reported to have good sensitivity and specificity for diagnosis of specific bacterial meningitis pathogens, have more recently been shown to contribute little to the management of most patients with suspected meningitis.¹² Polymerase chain reaction (PCR) of CSF for bacterial deoxyribonucleic acid (DNA) may be useful to confirm an etiologic diagnosis in culture-negative cases, especially those with prior antibiotic therapy, but is not routinely available in most hospitals. Elevated serum C-reactive protein (CRP) levels (>20 mg/L) and elevated serum procalcitonin (>0.5 ng/mL) are not specific for bacterial meningitis but had high predictive value in distinguishing between cohorts of children with bacterial and viral meningitis.¹² The level of soluble triggering receptor on myeloid cells in CSF has also been reported to distinguish between bacterial and viral meningitis.¹² Additional CSF studies may be useful for diagnosis of other specific infections such as CSF cryptococcal antigen and Venereal Disease Research Laboratory (VDRL) slide test.

Initial antibiotic therapy for suspected bacterial meningitis is most commonly initiated in the absence of culture and even Gram stain data. Initial empiric therapy must include agents active against the most likely pathogens based on the patient's age and underlying illnesses and modified for other specific risk factors such as nosocomial acquisition (Table 54.1). Treatment regimens must take into account local rates of antimicrobial resistance, particularly

rates of high-level resistance to penicillin and third-generation cephalosporins in *S. pneumoniae*. Standard regimens include vancomycin administered at doses targeted to achieve adequate CSF levels (serum troughs of 15 to 20 µg/mL) and a third-generation cephalosporin, either ceftriaxone or cefotaxime. In areas with increased rates of resistance to third-generation cephalosporins, rifampin may be added. When there is risk for *Listeria* infection based on age greater than 50 or on other specific risk factors such as alcoholism or altered immunity, high-dose ampicillin is included in the treatment regimen. For patients with nosocomial or postprocedure-related infections, cefotaxime or ceftriaxone may be changed to an agent with improved activity against nosocomial gram-negative organisms including *Pseudomonas aeruginosa*. Initial empiric therapy is modified on the basis of identification and susceptibility data of isolated pathogens. Standard recommended treatment durations are 7 days for meningococcal disease and *H. influenzae*, 10 to 14 days for *S. pneumoniae*, and 21 or more days for *Listeria*.^{1,5}

Studies in high-income countries have demonstrated the benefits of adjuvant dexamethasone in decreasing mortality rates and neurologic sequelae in patients with bacterial meningitis, and adjuvant steroids are now part of meningitis practice guidelines in the United States and Europe.^{5,13,14} In one large, randomized, placebo-controlled trial of 301 adults with suspected bacterial meningitis and cloudy CSF, adjuvant dexamethasone decreased mortality rates from 15% to 7% and decreased unfavorable outcomes from 25% to 15%.¹³ Benefits of corticosteroids were most evident in those with pneumococcal infection and those with a moderately impaired level of consciousness; patients with meningococcal disease had generally better outcomes with or without corticosteroids. More recent

Table 54.1 Treatment of Bacterial Meningitis in Adults*

Patient Group	Most Likely Pathogens	Empiric Antibiotic Therapy	Comments
Age 15-50 yr No risk factors [†]	<i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i>	Vancomycin + third-generation cephalosporin [‡]	Adjuvant dexamethasone [§]
Age 15-50 yr plus risk factors [†]	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>Listeria monocytogenes</i> , <i>Haemophilus influenzae</i>	Vancomycin + third-generation cephalosporin [‡] + ampicillin	Adjuvant dexamethasone [§]
Age >50 yr ± risk factors	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>L. monocytogenes</i> , aerobic gram-negative rods	Vancomycin + third-generation cephalosporin [‡] + ampicillin	Adjuvant dexamethasone [§]
Trauma, postneurosurgical, or other nosocomial infection	<i>Staphylococcus aureus</i> , coagulase-negative staphylococci, aerobic gram-negative rods	Vancomycin + <i>Pseudomonas</i> -active agent	Consider intrathecal therapy [¶]

*Patients older than 15 years of age.

[†]Risk factors: altered immunity including human immunodeficiency virus (HIV) infection and alcoholism.

[‡]Third-generation cephalosporin: ceftriaxone or cefotaxime; for highly penicillin-allergic patients an alternative would be aztreonam or a fluoroquinolone.

[§]Evidence for benefit of adjuvant dexamethasone is limited. Consider addition of rifampin in settings with high rates of cephalosporin resistance.

^{||} Includes cefepime or ceftazidime; alternatives include aztreonam, meropenem, and ciprofloxacin.

[¶]For multiresistant organisms or catheter-related infections. Most recent experience is with aminoglycosides or polymyxins.

Modified with permission from van de Beek D, de Gans J, Tunkel AR, et al: Community-acquired bacterial meningitis in adults. *N Engl J Med* 2006;354:44-53; and Tunkel AR, Hartman BJ, Kaplan SL, et al: Practice guidelines for the management of bacterial meningitis. *Clin Infect Dis* 2004;39:1267-1284.

trials from resource-limited settings including Malawi and Vietnam have failed to confirm the benefits of adjuvant steroids, even in those with documented pneumococcal infection, calling into question the generalizability of use of steroids in all settings.^{12,14} A recent meta-analysis was unable to clearly demonstrate benefits or harm with use of adjuvant corticosteroids.¹⁴ If steroids are to be used, the standard regimen based on published and animal studies is 10 mg of dexamethasone every 6 hours for 4 days and initiated prior to or concurrent with the first dose of antibiotics.^{1,5} Any benefit of steroids initiated after onset of antibiotic therapy is unknown. Patients with suspected or confirmed meningococcal meningitis should be placed in isolation to prevent nosocomial transmission via respiratory droplets for the first 24 hours of therapy. Meningococcal prophylaxis is indicated for household and other close contacts of meningococcal cases including first responders. Conversely, patients with Gram stains and clinical presentations consistent with non-meningococcal disease should also be quickly identified, to eliminate unnecessary use of meningococcal prophylaxis.

COMPLICATIONS, ICU MONITORING, AND PROGNOSIS

Patients with bacterial meningitis often require ICU monitoring either for complications evident at the time of presentation or for observation for complications that may subsequently develop during their course. Criteria for admission to an ICU have been proposed (Table 54.2)¹ and include sepsis and septic shock, respiratory compromise or pulmonary infiltrates, those with high risk of brain herniation, moderately impaired and deteriorating level of consciousness, new or evolving neurologic deficits, and presence of seizures. Some authorities feel that all patients with bacterial meningitis may benefit from intensive monitoring early on for presence of new neurologic signs or subtle seizures and for effective control of agitation.¹⁵ Patients with generally good outcomes can be defined early in their course on the basis of age, Glasgow Coma Score, APACHE II score, absence of focal neurologic abnormalities, and favorable laboratory features, but these stratification schemes will still fail to identify some patients with more complicated courses.^{2,16}

Major complications that occur during the course of bacterial meningitis have been summarized by van de Beek and colleagues^{1,2,12} and include deteriorating level of consciousness, which may be caused by development of meningoen- cephalitis (15% to 20% of cases), seizures (15% to 23%), brain edema (6% to 10%), and hydrocephalus (3% to 8%). Mannitol, hyperventilation, repeated lumbar punctures, prophylactic lumbar drainage, prophylactic ventriculostomy, and other modalities have all been proposed for management of increasing intracranial pressure. Increased pressure is associated with worse prognosis, but no single approach for treatment has been confirmed to be effective in all cases.^{1,17} Patients with severely increased pressure with impending herniation may require ventriculostomy with continuous CSF pressure monitoring. All patients should be monitored for seizures including nonfocal seizures that may only manifest as worsening level of consciousness, but routine use of prophylactic antiepileptic medication is not currently recommended.^{1,5} Focal neurologic deficits early in the course of meningitis are most often caused by

Table 54.2 Indications for Intensive Care Unit (ICU) Monitoring and Management for Bacterial Meningitis

Indication	ICU Management
Sepsis and shock	Hemodynamic support and monitoring, early goal-directed therapy
Pulmonary infiltrates or respiratory compromise	Airway management, monitoring of oxygenation, non-invasive or invasive ventilatory support
Glasgow Coma Scale score <10	Monitoring of examination; monitor for development of increased ICP, hydrocephalus, and seizures
Deteriorating level of consciousness	Monitoring of examination; monitor for development of increased ICP, hydrocephalus, and seizures
New or evolving neurologic deficits	Monitoring of examination; monitor for development of increased ICP, hydrocephalus, and seizures
Evidence of increased ICP	Consider intracranial pressure monitoring; osmotic diuretics
Acute hydrocephalus	Repeated lumbar puncture, lumbar drain, or ventriculostomy
Seizures	Continuous EEG monitoring, antiepileptic agents
Severe agitation	Careful sedation
Hyperglycemia	Maintain normoglycemic state with insulin therapy
Hyperpyrexia	Cooling modalities for fever >40° C

EEG, electroencephalogram; ICP, intracranial pressure.

Modified with permission from van de Beek D, de Gans J, Tunkel AR, et al: Community-acquired bacterial meningitis in adults. *N Engl J Med* 2006;354:44-53.

cerebrovascular complications or arteritis secondary to inflammation or less commonly to venous infarcts. The most common late neurologic complication is hearing loss, described in up to 20% of patients overall and in up to 34% of those with pneumococcal meningitis.^{1,2} The incidence of hearing loss may be decreased in dexamethasone-treated patients.¹³ Subdural empyema, brain abscess, and hemorrhage are all rare but potentially catastrophic complications of bacterial meningitis.

Repeat lumbar punctures are no longer routinely performed in patients with bacterial meningitis who are improving but are indicated in patients with worsening or suboptimal clinical response at 48 hours.⁵ Repeat CSF analysis is also indicated in patients with more resistant organisms such as highly cephalosporin-resistant *S. pneumoniae*, especially when treated with dexamethasone, because steroids may decrease antibiotic penetration into the CSF and delay sterilization.¹⁸ Repeat imaging by MRI or enhanced CT scan should be performed in patients with clinical deterioration or persistent decreased level of consciousness to assess for the complications listed earlier.

Overall mortality rates for bacterial meningitis are reported to be approximately 20% but vary by organism,

and an additional 14% will have moderate or major neurologic sequelae.¹ Prognosis for meningococcal meningitis is better than for pneumococcal infection. Late neuropsychiatric cognitive effects are seen in up to 10% of cases of bacterial meningitis.

ENCEPHALITIS

The other major CNS infectious syndrome besides bacterial meningitis that may present with fever, headache, altered sensorium, and meningeal signs is acute encephalitis, which is most commonly viral. Although there is significant overlap between clinical presentations of patients with bacterial meningitis and viral encephalitis, the presentation of viral encephalitis is dominated by evidence of parenchymal brain dysfunction including moderate to severely impaired sensorium, delirium, psychosis, focal neurologic findings, and seizures.^{19,20} The presence of meningismus is more variable, but most patients will have some evidence of meningeal enhancement on imaging and inflammatory cells in CSF.

A large number of viruses can cause encephalitis, but management strategies focus on the most common causes and those most likely to respond to specific interventions, particularly encephalitis caused by herpes simplex virus (HSV).^{19,22} Other important causes with worldwide distribution include other herpesviruses including varicella-zoster virus; Epstein-Barr virus; and cytomegalovirus (CMV), especially in immunocompromised patients.^{19,20,21} Influenza virus, mumps, measles, and enteroviruses such as enterovirus 71 are also important causes of acute viral encephalitis worldwide. Acute HIV infection can also occasionally present as a potentially treatable cause of fulminant meningoencephalitis.²¹ Acute presentations of progressive multifocal leukoencephaly caused by JC virus are also increasingly reported in HIV-infected and other immunocompromised patients.²³ In addition to those viruses seen worldwide, there are a variety of vector-borne viruses with regional and seasonal distributions.^{19,21} Important pathogens include eastern, western, and Venezuelan equine encephalitis; Japanese B encephalitis; St. Louis encephalitis; La Crosse encephalitis; and Nipah encephalomyelitis. Recently, West Nile encephalitis emerged as a major pathogen in the United States. West Nile first appeared in New York City in 1999, but cases are now distributed throughout the country, demonstrating the potentially unpredictable and dramatic spread of emerging vector-borne pathogens.^{24,25} Rabies, although extremely rare in developed countries, also needs to be considered in the differential diagnosis of fulminant encephalitis, both for its epidemiologic implications and because of recent reports of survival for patients with this previously universally fatal infection with aggressive ICU management protocols.²⁶ In addition to viral infections, many atypical bacteria, fungi, and protozoal organisms can present as acute meningoencephalitis.¹⁹ Particularly important to consider early in the differential diagnosis are infections that may respond to specific antimicrobial therapy including rickettsial diseases such as Rocky Mountain spotted fever (RMSF) and meningoencephalitis from spirochetal infections including neurosyphilis and Lyme disease.^{27,28} Important clues to these diseases include epidemiologic history and associated clinical features such as

rash. Data from the California Encephalitis Project, in which cases of suspected infectious encephalitis underwent an aggressive evaluation for a variety of infectious agents, suggest that the cause of at least 50% to 60% of cases of presumed infectious encephalitis remains undefined, and in 10% a noninfectious diagnosis was ultimately established.²⁹

Herpes simplex encephalitis is the most common sporadic cause of serious viral meningoencephalitis, causing 3% to 10% of cases of infectious encephalitis in adults and with an estimated frequency of about 1000 to 2000 cases per year in the United States.^{21,22,29} Ninety percent of cases are caused by HSV type 1, usually occurring in adults as reactivation disease and not primary infection; HSV type 2 commonly causes aseptic meningitis but much less commonly presents as fulminant encephalitis.^{22,30} Herpes encephalitis is an acute necrotizing process, typically causing hemorrhagic necrosis with particular predilection for the frontotemporal lobes and cingulate gyrus. Mortality rates are up to 70% in untreated cases, with 95% of those surviving having serious neurologic sequelae.^{21,22} Cases of herpes encephalitis beyond the neonatal period occur throughout life, but the highest case rates occur in younger individuals (younger than 20 years old) and in adults older than age 50 (half of cases). Presentation may include a prodromal viral syndrome in 50% of cases, followed by a generally rapid onset of headache, confusion, and altered level of consciousness. Meningismus, focal neurologic findings, and seizures are also common.^{20,22} In one series of patients with encephalitis, of which 37% were caused by HSV, focal CNS disease was much more likely than diffuse CNS disease to be caused by HSV.³¹ The approach to cases of suspected herpes encephalitis, as well as other viral or unknown encephalitides, includes early initiation of antiviral therapy and concurrent rapid clinical evaluation that includes imaging, CSF studies, and electroencephalogram (EEG) to establish a diagnosis.^{19,20,22} MRI is considered the imaging modality of choice. MRI is positive in more than 90% of cases, often showing changes of edema and necrosis in the medial temporal lobes, insular cortex, and cingulate gyrus as soon as 2 to 3 days into the illness.³² EEGs will be abnormal in nearly all cases, but early findings may be nonspecific and the characteristic periodic lateralizing epileptiform discharges may not be seen until later in the course.²² CSF findings include low- to moderate-grade lymphocytic pleocytosis in 85% and elevated protein in 80%; elevated red blood cell count and mildly decreased glucose are common but not universal, and cell counts may be completely normal in 8%.^{22,30} Likelihood of HSV encephalitis is extremely low with CSF WBC count of fewer than 5 cells/mm³ and protein levels of less than 50 mg/dL.³³ The International Herpes Management Forum has issued guidelines for confirmation of the diagnosis and for treatment.²² PCR of CSF for HSV DNA has replaced brain biopsy as the diagnostic method of choice for HSV encephalitis. Based on data from two trials comparing PCR with the gold standard of brain biopsy, sensitivity of PCR was 98% and specificity was 94% for diagnosing HSV encephalitis; the negative predictive value of PCR on CSF obtained more than 72 hours into the course of illness was close to 100% for excluding HSV.^{22,34,35} PCR has also expanded understanding of the range of clinical presentations of HSV encephalitis including recognition of

less severe cases.³¹ Viral culture has low sensitivity in older children and adults and is not recommended, and CSF and serum antibody studies have little role in the diagnosis.^{19,22} Treatment should be initiated on the basis of clinical suspicion pending PCR results using high-dose intravenous (IV) acyclovir at doses of 10 mg/kg every 8 hours and continued for 14 to 21 days, or until PCR results are available or an alternative diagnosis is established. Extrapolating from results in neonates, a positive CSF PCR for HSV at the end of treatment may be an indication to prolong therapy, especially if clinical response has been suboptimal.¹⁹

WEST NILE VIRUS ENCEPHALITIS

In the 12 years since it first appeared in the Western hemisphere, West Nile virus (WNV) has become a major infectious cause of invasive neurologic disease throughout the United States, with more than 1000 cases from 40 states reported in 2010.^{24,36} WNV is a mosquito-borne arbovirus affecting birds, mammals, and humans. Of human cases, 80% are asymptomatic and most of the remainder have West Nile fever, but 1% will develop neuroinvasive disease manifesting as meningitis, encephalitis, or a polio-like flaccid paralysis syndrome.^{24,25} Risk of encephalitis increases with age or with immunosuppression, particularly organ transplantation, and manifestations can range from mild disorientation to coma and death.²⁴ Parkinson-like tremors are also commonly reported. The flaccid paralysis syndrome, caused by viral infection of anterior horn cells, may have abrupt onset and patients may require prolonged ventilatory support. The fatality rate is 9% for WNV neuroinvasive syndromes, and survivors may have prolonged symptoms. In some patients, flaccid paralysis has not resolved after 1 to 2 years.²⁴ CSF findings of WNV are similar to those of other viral infections with lymphocytic pleocytosis predominating. Neuroimaging may be normal, but some scans may demonstrate abnormal signal in the basal ganglia, thalamus, and other deep brain structures or abnormal signal in anterior horn cells of the spinal cord.^{25,37} Diagnosis is confirmed by the finding of WNV-specific IgM antibodies in CSF and serum or by nucleic acid–based PCR of CSF, serum, or other fluids.^{19,24} Treatment is primarily supportive; multiple interventions including ribavirin, interferon (INF)- α , immunoglobulin, and other agents have been reported in individual cases and case series, but there are currently no good outcome data to support the use of any specific therapy.

BRAIN ABSCESS

Brain abscesses are focal infections of brain parenchyma, occurring from direct spread from local, contiguous infection (ear, sinuses, mastoid, bacterial meningitis); from hematogenous spread of infecting organisms from distant sites; or by direct inoculation from trauma or surgery.^{38,39} Modern imaging modalities have improved the initial management and follow-up care of patients with brain abscess, but it is less certain that this has significantly affected overall outcome. Presenting symptoms may be indistinguishable from those of other CNS infections, with fever, headache, and focal neurologic findings predominating.³⁸⁻⁴⁰ Seizures and decreased level of consciousness are also seen. Sepsis was noted in 18% of cases in one recent series.⁴¹ Duration of symptoms prior to presentation is typically much longer

than that of bacterial meningitis or viral encephalitis. Microbiology reflects the source of the original infection and most commonly includes streptococci, staphylococci, oral anaerobes, and enteric gram-negative organisms, but multiple other bacterial, fungal, tuberculous, and atypical organisms can also be found.³⁸⁻⁴⁰ In areas of high HIV prevalence, opportunistic brain infections, especially toxoplasmosis, have become more prevalent than typical pyogenic abscesses, and knowledge of HIV status is crucial to initial management of suspected infectious mass lesions.⁴²

The diagnosis of brain abscess is suggested by the clinical presentation and imaging findings by either CT or MRI showing enhancing parenchymal lesions, usually with surrounding inflammatory changes.^{38,39} Radiographic appearance may be indistinguishable from a malignant lesion. Management of suspected abscess includes either stereotactic aspiration or surgical drainage to both establish a microbiologic diagnosis and for primary treatment of the abscess. Smaller lesions (<1 cm) can be treated with antibiotics alone, but larger lesions will require either aspiration or open drainage.^{38,39} Recent studies have confirmed earlier findings that aspiration may result in lower mortality rates and less residual neurologic deficit than surgical resection.⁴³ Duration of treatment is until resolution of the abscess on serial imaging studies. Unlike bacterial brain abscesses, toxoplasmosis lesions in patients with AIDS are usually multiple and may respond to empiric toxoplasmosis therapy without need for further invasive diagnostic procedures.⁴²

SPINAL EPIDURAL ABSCESS

Spinal epidural infections most commonly arise by contiguous spread of infection into the spinal canal as a complication of vertebral infections or, less commonly, as a complication of epidural procedures such as epidural injections or epidural catheterization.⁴⁴⁻⁴⁶ Vertebral infections result from hematogenous infection of vertebral bodies or disk space or by direct introduction of organisms from surgery or trauma. In addition to affecting the vertebral bodies and intervertebral disk spaces, vertebral osteomyelitis may expand into surrounding paravertebral soft tissues and spinal canal and even rarely into the medullary spinal cord. Paravertebral and epidural infections can rapidly progress, resulting in severe neurologic symptoms from compression of nerve roots or the spinal cord, or by infarction of the spinal cord from inflammation and vasculitis of vertebral arteries.^{45,47} Thus an aggressive diagnostic and therapeutic approach is necessary to prevent catastrophic consequences such as irreversible paraplegia and death.

The incidence of spinal epidural infection from large retrospective reviews is reported as approximately 0.2 to 2 cases per 10,000 hospital admissions, but the frequency of this diagnosis may be increasing, perhaps because of improvements in radiographic diagnosis and increasing prevalence of risk factors.⁴⁵ Incidence in adults increases with age older than 30 years; important predisposing factors include diabetes, injection drug use, alcoholism, immunosuppression, underlying spinal disorders, trauma, invasive procedures, and extraspinal sites of infection that cause significant bacteremia.^{45,46} Infections can occur at any level of the spinal cord, although most series report predominance of lumbar involvement. Approximately two thirds of

infections are caused by *Staphylococcus aureus* including methicillin-resistant *S. aureus* (MRSA) with a variety of other gram-positive organisms (coagulase-negative staphylococci, viridans streptococci, β -hemolytic streptococci), as well as gram-negative organisms all reported in lesser numbers.⁴⁴⁻⁴⁶ Granulomatous infections including tuberculosis and brucellosis remain major causes of vertebral and epidural infection in many areas of the world.⁴⁷ Approximately 10% of episodes are culture-negative.⁴⁵

Presenting symptoms are extremely nonspecific and include back pain in more than 95% of cases and fever in two thirds of cases.^{44,45} Thirty percent of cases will present with evidence of early neurologic deficits such as muscle weakness, incontinence, or sensory deficits, and up to one third will have evidence of some paralysis on examination.⁴⁴⁻⁴⁶ Associated laboratory features include leukocytosis in two thirds of cases and elevated erythrocyte sedimentation rate (ESR) in nearly all cases. The most sensitive imaging modality is MRI with gadolinium, with reported sensitivity of greater than 95%, but most infections were also visualized on CT and unenhanced MRI.^{44,45} Standard therapy previously included emergent surgical drainage of the abscess and systemic antibiotic therapy. However, over the past 2 decades there has been an emerging literature on more conservative medical management employing percutaneous aspiration and antibiotics without open surgical drainage.⁴⁴⁻⁴⁶ These reports have suggested that outcomes are similar or better (i.e., less neurologic sequelae) compared to surgery.⁴⁴ No trials have directly compared treatment modalities, and retrospective analyses have not identified risk factors for worse outcomes with medical therapy alone. Indications for surgery include neurologic progression on treatment or lack of clinical response, thus those managed without surgery require careful monitoring.^{44,45} Surgery may also be the preferred treatment for those with more severe neurologic deficits on initial presentation, though these patients have worse outcomes overall regardless of treatment modality.^{44,45}

FULMINANT ENDOVASCULAR INFECTIONS

Infectious endocarditis and other endovascular infections are common causes of bacteremia and sepsis syndromes, and these patients are frequently admitted to critical care units for management of sepsis and other complications. Often, the diagnosis of endovascular infection is unsuspected, and initiation of appropriate treatment is delayed. Even relatively stable patients with bacterial endocarditis, especially those with left-sided endocarditis, require careful monitoring and management of potential major complications including heart failure and other cardiac events and septic emboli. The role of early surgical intervention has become increasingly appreciated in the management of complicated bacterial endocarditis, especially *S. aureus* endocarditis.

ACUTE INFECTIVE ENDOCARDITIS

Several large case series published since 2005 have addressed changes in the epidemiology of bacterial endocarditis over

the past 2 decades.^{48,49} The annual incidence of endocarditis of 5 to 7 cases per 100,000 has not changed significantly over time.⁴⁸ However, the International Collaboration on Endocarditis Prospective Cohort Study, a multicenter study of 1779 cases from 39 medical centers in 16 countries, has illustrated the recent changes in microbiology and clinical presentation of bacterial endocarditis.⁴⁹ In this cohort, as well as other recent cohorts, *S. aureus* rather than viridans streptococci were the predominant pathogens and increasing numbers of cases were considered either nosocomially acquired or health care associated.⁴⁹ *S. aureus* endocarditis is associated with a significantly higher mortality rate, higher rate of stroke and other systemic embolization, and higher rate of sustained bacteremia than endocarditis caused by other organisms.⁴⁹⁻⁵¹ The increased antibiotic resistance in organisms causing endocarditis, especially the increasing rates of MRSA, are reflected in the recent guidelines for diagnosis, treatment, and management of complications of endocarditis from the American Heart Association.⁵⁰ Other important recent epidemiologic trends are the decreased importance of congenital valvular and rheumatic disease as predispositions, the increasing age of cases, and the increased role of hemodialysis and indwelling cardiac devices such as pacemakers and implantable defibrillators as risk factors.⁴⁹⁻⁵²

Infectious endocarditis must be considered in the differential diagnosis of a broad range of clinical syndromes. Fever is the single most common presenting symptom, often accompanied by other constitutional symptoms of anorexia, weight loss, and fatigue. Onset may be acute or subacute with tendency toward more acute presentations with *S. aureus* infections. Signs and symptoms may be consequences of direct cardiac effects of infection including new or changing heart murmur, worsening congestive heart failure and valvular dysfunction, or onset of heart block from myocardial abscesses.⁵⁰ The clinical presentation may also be dominated by systemic manifestations of emboli or immune complex disease including such findings as skin lesions, splenomegaly, glomerulonephritis, cerebrovascular events, and other acute vascular embolic events. Patients with acute, fulminant endocarditis, particularly *S. aureus* endocarditis, may present with concurrent cardiogenic and septic shock.

Clinical criteria have been developed and prospectively evaluated for the diagnosis of infective endocarditis.^{53,54} The most current version of these, the Modified Duke Criteria for Diagnosis of Infective Endocarditis (Box 54.1), relies primarily on blood culture data and echocardiographic findings as the two major clinical criteria for diagnosis; additional minor clinical criteria (fever, underlying predisposition, embolic phenomena, immunologic phenomena) can also be used as supporting evidence for determining confirmed or suspected cases.⁵⁴ Patients with endocarditis have sustained bacteremia; in the absence of prior antibiotic therapy the yield of at least one positive blood culture after three sets are drawn is greater than 90%, and typically multiple cultures are positive. Thus two to three separate sets of blood culture should always be obtained in suspected endocarditis prior to initiation of therapy. Culture-negative cases may be attributed to prior antimicrobial therapy or to infection caused by fastidious or difficult-to-cultivate organisms.⁵⁰ Follow-up blood cultures are critical to document sterilization of blood and should be repeated frequently until

Box 54.1 Definition of Infective Endocarditis (IE) According to the Modified Duke Criteria**Definite IE****Pathologic Criteria**

Microorganisms demonstrated by culture or histologic examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen; OR

Pathologic lesions (as earlier) confirmed by histologic examination as showing active endocarditis

Clinical Criteria

2 major criteria OR

1 major and 3 minor criteria OR

5 minor criteria

Possible IE

1 major and 1 minor criteria OR

3 minor criteria

Rejected Diagnosis

Firm alternative diagnosis explaining evidence of IE; OR

Resolution of IE syndrome with antibiotic therapy for <4 days; OR

No evidence of IE at surgery or autopsy after antibiotic therapy <4 days; OR

Does not meet at least minimal criteria for possible IE

Definition of Terms Used in the Foregoing Criteria**Major Criteria**

Blood culture or other supportive microbiologic data for IE

Typical organisms consistent with IE (viridans streptococci, *Streptococcus bovis*, HACEK group,*

S. aureus, community-acquired enterococci) from two separate blood cultures in absence of a primary focus

Microorganisms consistent with IE from persistently positive blood cultures: at least 2 positive cultures drawn >12 hours apart; or all of 3 or a majority of ≥4 separate cultures drawn over at least 1 hour

Single positive blood culture or positive results on serologic testing for *Coxiella burnetii*

Evidence of endocardial involvement

Echocardiogram positive for IE defined as follows: oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation; or abscess; or new partial dehiscence of prosthetic valve or new valvular regurgitation (worsening or changing or preexisting murmur not sufficient)

Minor Criteria

Predisposition: predisposing heart condition or injection drug use (IDU)

Fever: temperature >38° C

Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway's lesions

Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, and rheumatoid factor

Microbiologic evidence: positive blood culture but does not meet a major criterion as noted earlier or serologic evidence of active infection with organism consistent with IE (excludes single positive culture for coagulase-negative staphylococci)

*HACEK: *Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, *Kingella*.

Modified from Li JS, Sexton DJ, Mick N, et al: Proposed modifications to the Duke Criteria for the Diagnosis of Infective Endocarditis. Clin Infect Dis 2000;30:633-638.

negative. Echocardiography should be performed on all patients with suspected endocarditis.^{50,52} When possible, transesophageal echocardiography (TEE) is the preferred modality in adults. Sensitivity of TEE is reported to be as high as 95% for native valve infection compared with 60% to 75% for transthoracic echocardiography (TTE) and is significantly better than TTE for diagnosis of prosthetic valve infection and for detection of complications such as perivalvular abscess that may affect management.⁵⁰ In children and uncomplicated adult cases, in which TTE is diagnostic, TEE may not be necessary. If initial studies are negative, TEE should be repeated in 7 to 10 days if clinical suspicion remains high.⁵⁰

Embolic complications may occur at any time during the course of infective endocarditis with overall incidence of 20% to 50%; risk decreases but still remains significant after initiation of antimicrobial therapy, especially with larger vegetations, and remains high for up to 2 to 3 weeks.^{50,55,56} Risks for embolization include specific organisms, especially *S. aureus*, *Candida*, HACEK* organisms, and *Abiotrophia*;

increased vegetation size (>10 mm) and mobility as determined by echocardiography; mitral versus aortic valve involvement; and anterior versus posterior location on the mitral valve.⁵⁰ More than half of clinically manifesting emboli involve the CNS, most commonly in the middle cerebral artery distribution.^{50,55} In addition to emboli, other risks for a fatal outcome include congestive heart failure, abnormal mental status, comorbid conditions, higher APACHE score, and *S. aureus* infection.⁴⁹⁻⁵¹ Congestive heart failure appears to have the highest association with death.⁴⁹⁻⁵¹ Medical therapy (versus surgical therapy) was also associated with higher 6-month mortality rates in recent studies.^{51,52}

The decision to perform emergent or urgent valvular surgery on patients with active endocarditis remains complex. Indications for surgery can be broadly classified into those related to management of heart failure, management of uncontrolled infection, and management of embolization, and decisions are also impacted by patient status and available surgical expertise. Traditional indications for surgery include refractory congestive heart failure; persistent infection despite optimal antimicrobial therapy; fungal or other difficult-to-treat organisms; one or more emboli during the first weeks of antimicrobial therapy; and valvular

*HACEK is an acronym formed from the names of bacteria involved: *Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, and *Kingella* spp.

Table 54.3 Possible Indications for Emergent or Urgent Surgical Intervention for Acute Infective Endocarditis

Indication	Details/Comments
Clinical Indications	
Refractory congestive heart failure Severe valvular decompensation	Most common single indication for surgery Usually acute mitral or aortic insufficiency but also valve obstruction. Less commonly, severe tricuspid regurgitation
Emboli and recurrent emboli	Especially with 1 or more events occurring during first 1 to 2 weeks of antimicrobial therapy
Persistent infection/sepsis	Persistent positive blood cultures after 7 days of optimal antibiotic treatment and no other source
Difficult-to-eradicate organisms	Fungal endocarditis, highly resistant bacteria; staphylococcal or gram-negative prosthetic valve endocarditis (controversial)
Extension of infection into myocardium	Evidence of new heart block, echocardiographic findings as listed below
Echocardiographic Indications	
Evidence of valve decompensation Vegetation characteristics	Dehiscence, rupture, perforation, fistula, perivalvular abscess >10 mm in size, especially on anterior mitral valve and emboli; increase in size despite treatment; >15 mm in size on aortic, mitral, or prosthetic valve; >20 mm in size on tricuspid valve
Other Possible Indications	
Complicated prosthetic valve infection ?Any left-sided <i>Staphylococcus aureus</i> infection	As defined by TEE findings; high failure rate for medical therapy alone Early surgical management may be associated with lower mortality

TEE, transesophageal echocardiography.

Modified from Baddour LM, Wilson WR, Bayer AS, et al: Infective endocarditis: Diagnosis, antimicrobial therapy, and management of complications, a statement for healthcare professionals from the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young, and the Councils on Clinical Cardiology, Stroke, and Cardiovascular Surgery and Anesthesia, American Heart Association. *Circulation* 2005;111:e394-e433; and Thuny F, Grisoli D, Collart F, et al: Management of infective endocarditis: Challenges and perspectives. *Lancet* 2012;379 (9819): 965-975.

complications of dehiscence, perforation, fistula, and large perivalvular abscesses (Table 54.3).⁵⁰ Vegetation size and location are also emerging as possible independent indications for surgery.⁵⁰ The risk of infecting a new prosthetic valve during surgery for active endocarditis is only 2% to 3%; thus active infection is not a contraindication to surgery that is indicated for complications associated with high mortality rate.⁵⁰ Reviews of recent studies have confirmed the decreased mortality rates of cohorts of patients who were managed with early surgical intervention, especially those with left-sided *S. aureus* endocarditis, though there are no randomized controlled trials completed that address this.^{50,52} The optimal surgical procedure and the role of more conservative procedures such as vegetation resection remain incompletely defined, though resection of vegetations is frequently done in isolated, refractory right-sided endocarditis. The majority of patients who survive an episode of left-sided endocarditis who are not operated on initially will ultimately require valve replacement within the next 15 years.⁵⁰

Anticoagulation in patients with active endocarditis can present difficult management dilemmas. Anticoagulation has been considered to be relatively contraindicated in active endocarditis because of the risk of hemorrhagic CNS events.^{50,57} However, data from a recent case cohort study suggest that risk of warfarin therapy in acute left-sided native valve endocarditis has been overestimated.⁵⁷ In

patients already on anticoagulation for mechanical valves or other specific indications, warfarin should be switched to heparin therapy during the initial phase of therapy, especially in cases in which surgical intervention is being considered. Anticoagulation should be discontinued if possible after acute CNS embolic events. Neurologic events, most commonly embolic events but also mycotic aneurysms, are the second leading cause of death in acute endocarditis after heart failure. Decisions on timing of surgery and management of anticoagulation perioperatively and postoperatively in patients with CNS events are particularly challenging.

Optimal antibiotic therapy for patients with infective endocarditis is outlined in the American Heart Association guidelines, though there are more recent specific recommendations for treatment of MRSA valvular infections.^{50,58} Individual treatment regimens including choice of antibiotic, need for combination therapy, and duration of therapy are based on the organism, susceptibility data, location of infected valve, and whether the infection is complicated or uncomplicated. Left-sided *S. aureus* endocarditis is generally treated for 6 weeks with a parenteral β -lactam or vancomycin. Addition of gentamicin for native valve disease is no longer recommended due to risk of nephrotoxicity.⁵⁹ MRSA infections require treatment with vancomycin or daptomycin. Uncomplicated right-sided endocarditis in injection drug users may have a more benign course, and there is

evidence for use of shorter courses of therapy and even for use of oral therapy in selected patients. Treatment of viridans streptococcal endocarditis is 4 weeks of a β -lactam or vancomycin, and gentamicin is added for disease caused by relatively penicillin-resistant strains. Selected patients with uncomplicated viridans streptococcal infections have been treated with 2 weeks of combination therapy. β -Lactam therapy for susceptible isolates is always preferred to vancomycin in nonallergic patients. Enterococcal endocarditis is usually treated for 4 to 6 weeks with synergistic combinations of a penicillin or vancomycin and an aminoglycoside, but regimens need to be modified on the basis of strain resistance patterns in view of increasing rates of penicillin, vancomycin, and high-level aminoglycoside resistance. Prosthetic valve infections require longer treatment courses and use of combination therapy, and failure rates of medical therapy for prosthetic valve disease are high.⁵⁰

DEVICE-RELATED ENDOVASCULAR INFECTIONS

Endovascular infections other than valvular infections have become increasingly common as causes of bacteremia and sepsis. This is related to the increased use of indwelling devices including vascular catheters for chemotherapy and other long-term parenteral therapies, use of accesses for hemodialysis, and the expanding indications for implantable cardiac devices for patients with congestive heart failure and arrhythmias. Infection is the most common serious complication of peripherally inserted central venous catheters (PICCs), tunneled catheters, and totally implanted intravascular devices.⁶⁰ Patients presenting with sepsis and focal findings related to the catheter such as tunnel infection, port abscess, or cellulitis; those with associated venous thrombosis; and those with concurrent endocarditis or osteomyelitis require removal of the catheter.⁶⁰ Management is more difficult in patients with sepsis or bacteremia without local signs of infection when removal of the catheter is not a trivial procedure. Diagnosis of the catheter as the source of a bacteremia can sometimes be made with use of paired central and peripheral blood cultures. Positive central and negative peripheral cultures or central cultures that are positive significantly earlier than peripheral cultures implicate the catheter as the source.⁶⁰ The majority of infected permanent catheters require removal; selected uncomplicated catheter infections in nonseptic patients whose bloodstream has sterilized on antibiotics can be treated with catheter retention and antibiotic therapy, especially infections caused by coagulase-negative staphylococci and other less virulent organisms.⁶⁰ Algorithms for the management of suspected and confirmed line infections in patients with long-term access devices are shown in [Figure 54.2A](#). Antibiotic lock therapy is a strategy in which antibiotic solutions are used to fill the catheter lumen to maintain high antibiotic concentrations in the catheter and catheter hub and yield higher rates of catheter salvage than parenteral antibiotics alone.⁶⁰ Hemodialysis catheter infections pose particular management challenges because of the high prevalence of infection in these patients as well as the need to preserve dialysis access. An algorithm for management of tunneled hemodialysis catheters is shown in [Figure 54.2B](#). Hemodialysis has emerged as a major risk factor for endocarditis in recent studies. Catheter salvage strategies

and guidewire exchange strategies are employed more frequently in hemodialysis catheter-associated infections than in other populations.^{60,61}

Indications for placement of implantable cardioverter-defibrillator devices (ICDs) in patients with cardiac disease have recently been expanded, resulting in increased number of ICDs and increased prevalence of pacemaker and ICD infections.^{62,63} Rates of pacemaker and ICD infections have increased out of proportion to increased rates of utilization of these devices, and in population-based studies infection rates range from 1 to 3 infections per 1000 device years.⁶² Infections include site and generator pocket infections and infections of the leads. Lead infections, which account for probably half of all infections, may be complicated by sepsis and septic shock, suppurative thrombophlebitis, and endocarditis and almost always require explantation of the device.⁶² Diagnosis is typically made by blood cultures and TEE, which may show vegetations on the leads or associated endocarditis. The most common organisms are coagulase-negative staphylococci and *S. aureus* in 80% of cases. Most infected leads can now be removed through percutaneous extraction procedures rather than open surgical explantation, but the expertise and technology for this are not available at all hospitals. Devices should not be replaced until bacteremia has completely resolved.

PRIMARY BACTEREMIAS

In 10% to 30% of patients presenting from the community with bacteremia and sepsis, the primary source of the bacteremia remains unknown, even after careful clinical and radiographic evaluation.^{64,65} This includes patients with infections manifesting with a primary bacteremia, as well as those with probable secondary bacteremia from an occult focus. Bacteremia of unknown cause is associated with higher mortality rate.⁶⁴ Primary bacteremias are more common with certain microorganisms and with specific host predispositions. These syndromes, if unrecognized, have particularly high morbidity and mortality rates. Patients with impairment in immunoglobulin production or function and impaired or absent splenic function are predisposed to infections with encapsulated organisms such as *S. pneumoniae*, *N. meningitidis*, *H. influenzae*, and group B streptococcus.⁶⁶ Patients with advanced liver disease and cirrhosis are predisposed to these, as well as a variety of other spontaneous bacteremias.⁶⁷ Patients with cell-mediated immune defects may present with other unusual bacteremias such as *Listeria* and *Salmonella* sepsis. Severe neutropenia greatly increases the risk of spontaneous bacteremia and sepsis from endogenous gastrointestinal flora, and the management of fever in neutropenic patients includes empiric initiation of broad-spectrum antibacterial therapy.⁶⁸ Several important specific bacteremia syndromes are described as follows.

MENINGOCOCEMIA AND MENINGOCOCCAL SEPSIS

Invasive meningococcal disease can present as either bacterial meningitis or as the syndrome of meningococemia with meningococcal sepsis without meningitis.⁷ The

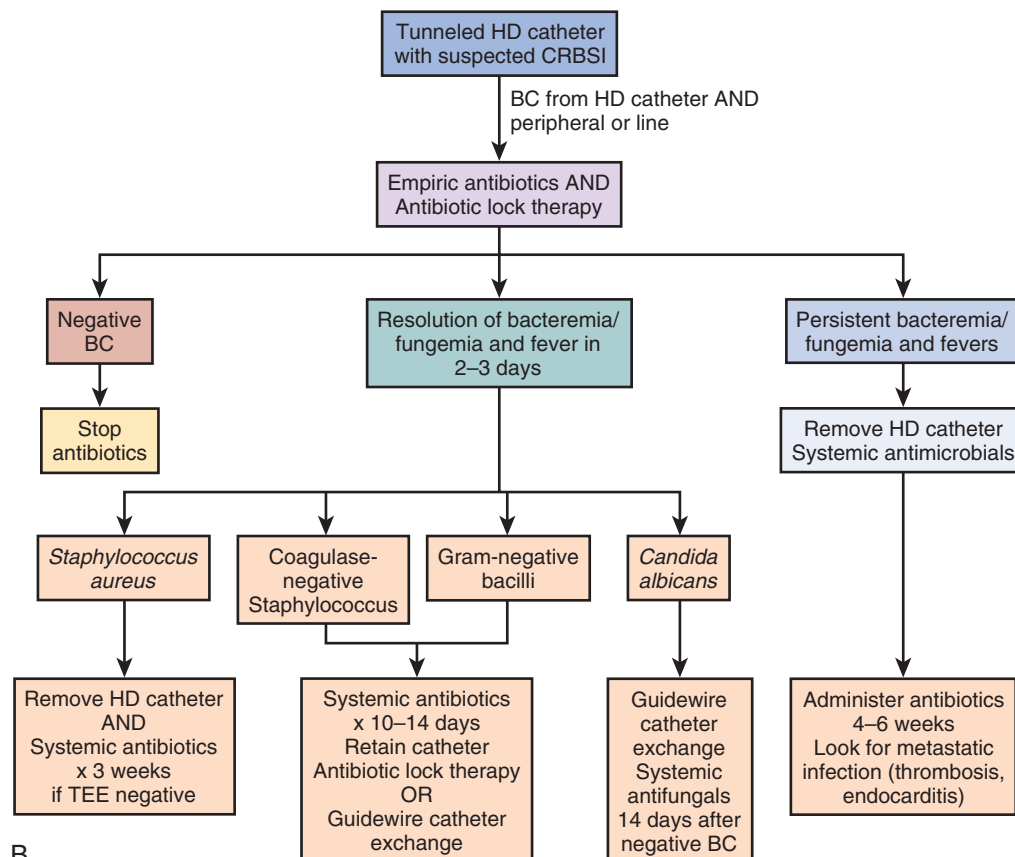

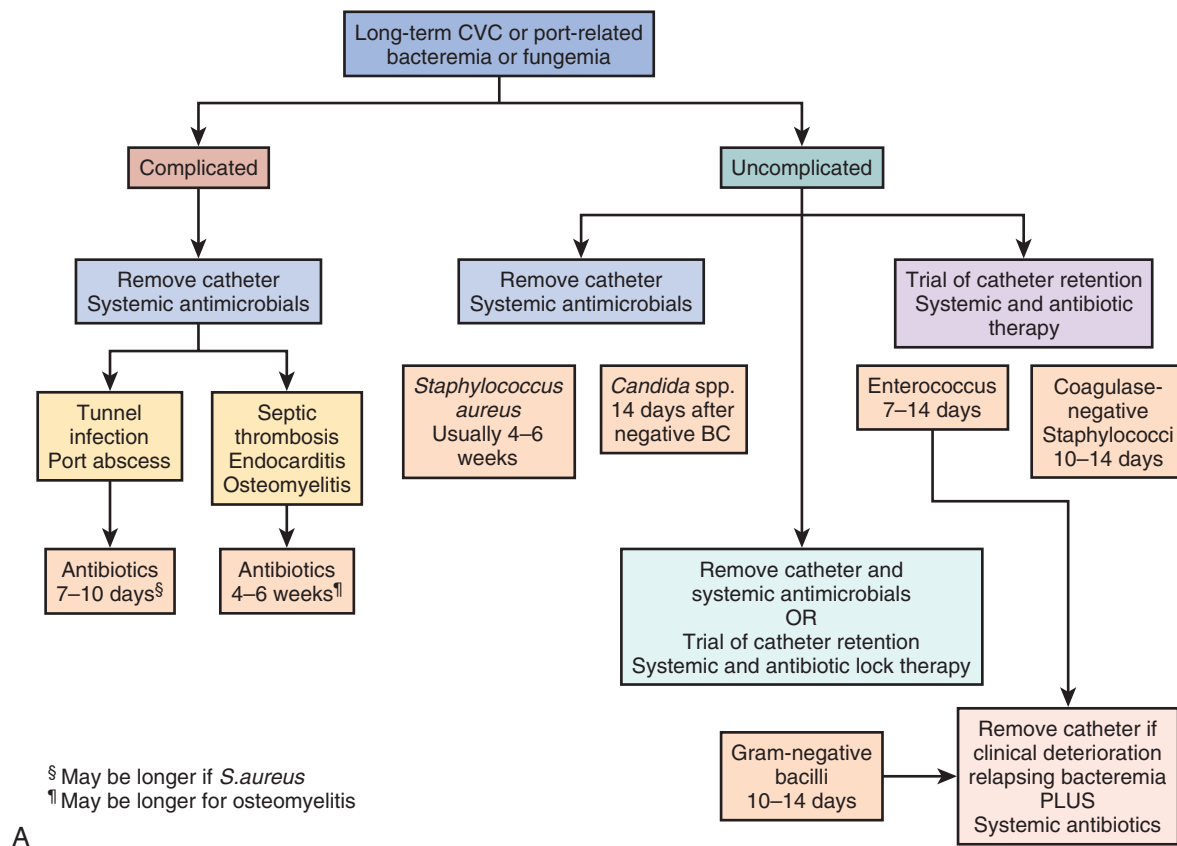

Figure 54.2 Algorithms for management of catheter-related bloodstream infection (CRBSI) in bacteremic patients with long-term central venous catheter or ports (**A**) and for suspected CRBSI in patients with tunneled hemodialysis catheters (**B**) including indications for removal versus attempt at salvage of infected indwelling long-term catheters. BC, blood culture; TEE, transesophageal echocardiography. (Data from Mermel LA, Alon M, Bouzon E, et al: Clinical practice guidelines for the diagnosis and management of intravascular catheter-related infection: 2009 update by the Infectious Diseases Society of America. Clin Infect Dis 2009;49(1):1-45.)

proportion of primary meningococemia cases and severity of disease manifestations depend in part on the serotypes present in the community but are also heavily influenced by host genetic makeup. The annual incidence of meningococcal disease in the United States is approximately 1 case per 100,000, with mortality rate of 10% to 14% and significant residual morbidity in up to 20%.⁷ Besides young children, adolescents and young adults ages 11 to 19 are at increased risk for meningococcal disease, but risk persists throughout life and is increased in those with certain immune deficiencies such as terminal complement deficiency and cirrhosis.⁷ Patients with meningococemia present with fever, headache, malaise, vomiting, and myalgias.^{69,70} Most patients will also present with rapid development of a characteristic non-blanching petechial or purpuric rash, but the rash can be maculopapular or absent. Early symptoms that may be important clues to the diagnosis are leg pains and cold hands and feet.⁶⁹ If untreated, disease may progress rapidly within 24 hours to fulminant purpura and hemorrhagic shock. The keys to improved outcome are early recognition and aggressive therapy. Early institution of antibiotic therapy with a penicillin or third-generation cephalosporin can significantly improve outcomes. PCR of blood is useful for diagnosis, especially in patients who received antibiotics prior to hospitalization.^{7,69} A tetravalent conjugated polysaccharide vaccine is available in the United States and is recommended for routine vaccination of older children and adolescents and other high-risk populations.⁷

PRIMARY PNEUMOCOCCAL BACTEREMIA

Pneumococcal bacteremia is most commonly a consequence of pneumococcal pneumonia, but 5% to 10% of episodes occur without an identified underlying focus.⁷¹ Severe episodes may present with fulminant sepsis and purpura fulminans clinically indistinguishable from meningococcal sepsis. Important risk factors for pneumococcal sepsis include asplenia and hyposplenism, HIV infection, sickle cell disease, alcoholism, malignancy, and other immunocompromised states, although this syndrome can occur in otherwise healthy adults and children without predisposing risks.⁷² *S. pneumoniae* causes 50% to 90% of cases of the fulminant sepsis syndrome that occurs in postsplenectomy or functionally asplenic patients.⁶⁷ Other causes of the postsplenectomy sepsis syndrome include *N. meningitidis*; *H. influenzae*; and, less commonly, *Capnocytophaga canimorsus*, *Escherichia coli*, *Salmonella*, and the vector-borne parasitic infections malaria and babesiosis. Immunization with pneumococcal, meningococcal, and *H. influenzae* vaccines is recommended for those at risk for postsplenectomy sepsis.⁶⁶

STAPHYLOCOCCUS AUREUS BACTEREMIA

S. aureus bacteremia can occur from localized staphylococcal disease such as skin and soft tissue infection or pneumonia, endovascular infection, and endocarditis. It can also be of occult origin. Regardless of the initial source of bacteremia, there is significant risk for development of late complications including endocarditis, bone and joint disease, infections of prosthetic devices, or other metastatic foci in up to one third of cases.^{58,73} Features associated with complicated *S. aureus* bacteremia include prolonged bacteremia,

prolonged fever, and embolic lesions. Longer-course therapy (at least 4 weeks) is recommended for patients with complicated disease, whereas 2 weeks of treatment may be adequate for selected patients with uncomplicated bacteremia when endocarditis has been excluded.⁷⁴ TEE is recommended to exclude endocarditis in patients with otherwise clinically uncomplicated *S. aureus* bacteremia when short-course therapy is being considered.^{73,74}

TOXIN-MEDIATED INFECTIONS

STAPHYLOCOCCAL TOXIC SHOCK SYNDROME

S. aureus produces multiple virulence factors that contribute to its success as a human pathogen. These virulence factors potentiate local adherence, tissue invasion, and avoidance of host defenses, all features that are important in the pathogenesis of localized skin and soft tissue infection, pneumonia, bacteremia, and metastatic infections. Staphylococci also produce a variety of exotoxins that are released into the systemic circulation to act at distant sites.⁷⁵ Some of these exotoxins are directly pathogenic to specific cells, such as exfoliatin B, which causes staphylococcal scalded skin syndrome. Other exotoxins function as potent superantigens, antigens that bypass the intermediate T-cell antigen processing steps by binding directly to V β domains on T-cell receptors. This causes direct activation of multiple T-cell classes resulting in unopposed release of large amounts of cytokines including interleukin (IL) 2, IL-4, IL-6, IFN- γ , TNF- α , and IL-1 β .⁷⁵ The resulting “cytokine storm” can lead to septic shock, multiorgan failure, and death.

The most well-studied staphylococcal superantigens are the pyrogenic antigens TSST-1 and TSST-2 and enterotoxins B and C. TSST-1 and TSST-2 are the primary exotoxins causing the staphylococcal toxic shock syndrome.⁷⁵ First described in 1979 as a unique syndrome primarily associated with menstruating women using super absorbent brands of tampons, staphylococcal toxic shock syndrome is now known to occur potentially from infection or colonization at any site with an exotoxin-producing strain.^{76,77} Disease is associated with conditions leading to exotoxin production in a host who lacks preexisting antibodies to TSST-1. The overall incidence of this syndrome, as well as the proportion of cases associated with menstruating women, has decreased since 1980.⁷⁶ Toxic shock syndrome is characterized by the acute onset of fever, hypotension, myalgia, scarlatiniform or erythroderma-like rash, nausea, vomiting, diarrhea, and development of multiple-organ failure including renal failure, elevated liver enzymes, and disseminated intravascular coagulopathy.^{76,77} Typically the rash will evolve and cause late desquamation of hands and feet. Specific criteria for the diagnosis of staphylococcal toxic shock syndrome have been described (Box 54.2).⁷⁶ Treatment is primarily supportive, but antistaphylococcal agents are administered to treat the underlying staphylococcal colonization or infection; some evidence suggests that immunoglobulin may be beneficial by binding exotoxin and attenuating the cytokine response. Staphylococcal strains producing the staphylococcal enterotoxins B and C have been implicated in some nonmenstrual-associated cases.⁷⁵

Box 54.2 Criteria for Diagnosis of Staphylococcal and Streptococcal Toxic Shock Syndromes

Staphylococcal Toxic Shock—CDC Criteria

1. Fever $>38.9^{\circ}\text{C}$ or $>102^{\circ}\text{F}$
2. Rash (diffuse macular erythroderma)
3. Desquamation 1-2 weeks after onset, particularly of the palms and soles
4. Hypotension: systolic blood pressure $<90\text{ mm Hg}$ for adults or orthostatic hypotension
5. Multisystem involvement with 3 or more of the following:
 Gastrointestinal: vomiting or diarrhea at onset of illness
 Muscular: severe myalgia or CK levels at least $2\times$ upper limit of normal
 Mucous membrane: vaginal, oropharyngeal, or conjunctival hyperemia
 Renal: BUN or serum creatinine at least $2\times$ upper limit of normal or >5 leukocytes per high-power field without UTI
 Hepatic: total bilirubin, AST, or ALT at least $2\times$ upper limit of normal
 Hematologic: platelets $\leq 100,000/\text{mL}$
 CNS: disoriented or alterations in level of consciousness without focal neurologic signs when fever and hypotension are absent
6. Negative results on tests, if obtained
 Blood, throat, or cerebrospinal fluid cultures (blood may be positive for *S. aureus*)
 Rise in body titer to Rocky Mountain spotted fever, leptospirosis, or measles antigen

Case Classification

Probable: 5 of the 6 clinical findings above

Confirmed: All 6 clinical findings including desquamation

Streptococcal Toxic Shock Syndrome

- A. Isolation of group A streptococci
 1. From a sterile body site
 2. From a nonsterile body site
- B. Clinical signs of severity
 1. Hypotension
 2. Clinical and laboratory abnormalities (2 or more):
 Renal impairment
 Coagulopathy
 Liver abnormalities
 Acute respiratory distress syndrome
 Extensive tissue necrosis (i.e., necrotizing fasciitis)
 Erythematous rash

Case Classification

Definite: A1 plus B (1 + 2)

Probable: A2 plus B (1 + 2)

ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CDC, Centers for Disease Control and Prevention; CNS, central nervous system; CK, creatine kinase; UTI, urinary tract infection.

Modified from Haijeh RA, Reingold A, Weil A, et al: Toxic shock syndrome in the United States: Surveillance update, 1979-1996. *Emerg Infect Dis* 1999;5:807-810; and Stevens DL: Streptococcal toxic-shock syndrome: Spectrum of disease, pathogenesis, and new concepts in treatment. *Emerg Infect Dis* 1995;1:69-78.

STREPTOCOCCAL TOXIC SHOCK SYNDROME

Group A β -hemolytic streptococci are also capable of producing a toxic shock–like syndrome analogous to staphylococcal toxic shock syndrome.^{78,79} Most often this is seen in the setting of severe bacteremic streptococcal soft tissue infection or with streptococcal necrotizing fasciitis. In one large survey of invasive streptococcal infections in Ontario, 13% were complicated by toxic shock syndrome, and the mortality rate of these infections was 81%.⁷⁹ The pathogenesis of this syndrome is attributed to streptococcal pyrotoxins functioning as superantigens but may also involve binding of streptococcal M protein-fibrinogen complexes to PMN cells causing PMN activation and endothelial damage. Clinical criteria for the diagnosis of streptococcal toxic shock syndrome have been defined (see Box 54.2).⁷⁸ In addition to use of antibiotics that decrease toxin production in vitro, such as clindamycin and linezolid, IV immunoglobulin (IVIG) has been used for treatment though clinical evidence for benefit of IVIG is limited.⁸⁰ Other streptococcal species have also been reported to produce a toxic shock–like illness including viridans streptococci; groups B, C, and G β -hemolytic streptococci; and *Streptococcus suis*.

CLOSTRIDIAL TOXIC SHOCK SYNDROME

A rare, generally fatal syndrome of toxic shock has been reported following medical abortion with oral mifepristone and vaginal misoprostol.⁸¹ This syndrome has also been seen complicating endometritis after live births and is due to *Clostridium sordellii*. Clinical findings include tachycardia, hypotension, edema, hemoconcentration, and profound leukocytosis, and generally the absence of fever. Optimal management of this syndrome remains poorly defined.

TETANUS

Tetanus is a syndrome of increased muscle rigidity and convulsive spasms caused by a toxin produced by the environmental spore-forming anaerobic bacterium *Clostridium tetani*.⁸² Since the introduction of routine immunization, tetanus has become increasingly rare, with the number of U.S. cases decreasing from 560 cases in 1947 to only 233 cases from 2001 to 2008 with case fatality rate of 13%.⁸² Clinical disease is caused by contamination of wounds, most commonly traumatic wounds, with bacterial spores. Spores then germinate and produce toxins including tetanospasmin, a highly potent neurotoxin that inhibits neurotransmitter release, resulting in blockage of inhibitor impulses and unopposed muscle contractions. Cases predominate in the summer or wet season, and disease is now most commonly seen in older adults because of either missed primary immunization or waning effects of childhood immunization.⁸² The most common syndrome is that of generalized tetanus with descending symptoms of trismus (lockjaw), difficulty swallowing, muscle rigidity, and spasms. Symptoms may persist for several weeks, and complete recovery may take months. Complications include laryngospasm, fractures, hypertension, nosocomial infections, and death. Treatment is primarily supportive, although metronidazole or penicillin may be given to treat potentially infected or colonized wounds. Patients require admission to an ICU for

control of rigidity and spasms with benzodiazepines or neuromuscular blocking agents and for ventilator support. Human tetanus immunoglobulin may be administered, but this only binds free toxin, so there may be little benefit by the time of clinical presentation. Routine childhood and adult immunization with tetanus toxoid remains the primary strategy for preventing this rare but often fatal condition. Guidelines for use of immunoglobulin and vaccination in management of potentially infected wounds have been published.⁸²

BOTULISM

Clostridium botulinum is an anaerobic spore-forming bacterium that produces botulinum toxin, a family of closely related but immunologically distinct polypeptide toxins that are among the most potent neurologically acting poisons known.⁸³ Other, less common clostridial species can also produce botulinum toxin. Botulinum toxin binds irreversibly to synaptic complexes, affecting ganglionic synapses, presympathetic synapses, and neuromuscular junctions. Clinical syndromes include those caused by ingestion of preformed toxin such as food botulism and those resulting from acquisition of the organism and production of toxin in vivo such as infant botulism in very young children and wound botulism from contaminated wounds, most commonly seen in injection drug users. Patients present initially with cranial nerve dysfunction and evolve to descending paralysis without sensory or cognitive effects. Diagnosis is made on clinical grounds; testing of food products or human samples in the United States is performed by the Centers for Disease Prevention and Control (CDC). Treatment is primarily supportive, but equine type-specific antitoxin is available through the CDC.⁸³ Antitoxin is only effective in binding free toxin if given in the first 72 hours. Because of its potency, environmental stability, and potential for aerosolization, botulinum toxin is considered a potential agent of bioterrorism.⁸³

DIPHTHERIA

Diphtheria is caused by toxigenic strains of the bacterial species *Corynebacterium diphtheriae*. This disease has become extremely rare in the United States secondary to universal vaccination with diphtheria toxoid vaccine, with an average of one confirmed case per year.⁸⁴ Patients with respiratory diphtheria present with sore throat; low-grade fever; occasional neck swelling; and the characteristic grayish adherent membrane covering the tonsils, throat, or nose.⁸⁴ Complications include myocarditis, polyneuritis, and airway obstruction, with mortality rates of 5% to 10%. Outbreaks of diphtheria continue to occur in many parts of the world.

SERIOUS SKIN AND SKIN STRUCTURE INFECTIONS

Serious skin and soft tissue infections are characterized by rapidly progressive inflammation and necrosis of skin, subcutaneous fat, and fascia. Occasionally, muscle is also involved. Several terms have been used to describe these infections: *necrotizing fasciitis*; *synergistic necrotizing cellulitis*;

progressive bacterial synergistic gangrene; *anaerobic cellulitis*; and, when muscle is involved with clostridial infection, *clostridial myonecrosis (gas gangrene)*.⁸⁵ Differentiating among these entities is difficult and somewhat artificial. A variety of features of some of the most important necrotizing skin and soft tissue infections are shown in Table 54.4. Microbiologically, these infections may be caused by a single pathogen such as group A β -hemolytic streptococcus; however, they are more frequently polymicrobial in nature. Risk factors for these infections include diabetes, old age, peripheral vascular disease, malignancy, alcoholism, renal failure, and immunosuppressive therapy. Infection may follow traumatic injuries that become contaminated by soil. The primary traumatic event may be relatively minor. Initial signs and symptoms may be similar to a severe cellulitis. Early findings include fever, tachycardia, moderate to severe pain, and swelling and induration of the skin.⁸⁶ Late findings include severe pain or even anesthesia, skin necrosis, hemorrhagic bullae, crepitus, drainage, and signs of systemic inflammatory response syndrome or severe sepsis including multiorgan failure.⁸⁶ Laboratory tests usually demonstrate leukocytosis and metabolic acidosis. Plain radiographs may reveal gas in the soft tissues. CT or MRI is useful in delineating extent of disease or the presence of soft tissue gas. Diagnostic evaluation should also include blood cultures, Gram staining of tissue exudates, and aerobic and anaerobic cultures obtained at surgery or from a needle aspiration. Incision and exploration or biopsy can even be done at the bedside to obtain material for Gram stain, culture, and histologic evaluation.

Once a necrotizing soft tissue infection has been identified, prompt therapy is important. Early aggressive surgical débridement is essential.⁸⁷ Because most cases of necrotizing skin infection are polymicrobial, empiric antibiotic coverage should be sufficiently broad spectrum to cover gram-positive cocci, gram-negative bacilli, and anaerobes. A reasonable empirical regimen might consist of a β -lactam/ β -lactamase inhibitor or a carbapenem combined with vancomycin or another agent effective against MRSA. Antibiotic therapy can subsequently be adjusted on the basis of results of cultures and sensitivities.⁸⁸ In cases of group A β -hemolytic streptococcal infection, penicillin plus clindamycin is the therapy of choice. Clindamycin is effective in turning off toxin production. Linezolid also has similar activity.⁸⁹ IVIG may be a useful adjuvant therapy for streptococcal toxic shock.^{80,90}

NECROTIZING FASCIITIS

Necrotizing fasciitis is an uncommon, severe infection that causes necrosis of the subcutaneous tissue and fascia with sparing of the underlying muscle. Two predominant types, based on microbiology, are described. In type I, at least one anaerobic species is isolated along with one or more facultative anaerobes and members of the Enterobacteriaceae.^{85,91} This form of necrotizing fasciitis most commonly affects the extremities but may involve the abdominal wall, postoperative wounds, perianal area, and groin. It occurs following trauma or a variety of surgical procedures, perirectal abscess, decubitus ulcer, or perforation of the intestines. Patients at increased risk include those with diabetes mellitus, alcoholism, and injection drug use. The involved area is initially

Table 54.4 Differentiating Features of Necrotizing Skin and Soft Tissue Infections

Feature	Progressive Bacterial Synergistic Gangrene	Nonclostridial Anaerobic Cellulitis	Clostridial Myonecrosis (Gas Gangrene)	Necrotizing Fasciitis Type 1	Necrotizing Fasciitis Type 2
Risk factors	Surgery, ileostomy, colostomy, chronic ulceration	Diabetes mellitus	Trauma, surgery	Diabetes mellitus, surgery, perineal infection	Trauma, surgery, none
Microbiology	Microaerophilic streptococci plus <i>Staphylococcus aureus</i>	Non-spore-forming anaerobes ± coliforms, streptococci, <i>S. aureus</i>	<i>Clostridium</i> spp.	Polymicrobial (Enterobacteriaceae plus anaerobes)	Group A streptococci
Course	Slow	Slow or rapid	Very rapid	Rapid	Very rapid
Pain	++++	++/+++	++++	+++ /++++	++++
Gas formation	—	++++	++	++	—
Appearance	Central necrotic ulcer, erythematous periphery	Erythematous skin necrosis	Bullae, necrosis	Bullae, skin	Bullae, necrotic skin and tissue
Drainage	Purulent if present	Purulent	Serosanguineous	“Dishwater,” seropurulent	Serous if present
Depth of involvement	Skin, soft tissue	Skin, soft tissue	Muscle	Fascia	Fascia
Systemic toxicity	±	+++ /++++	++++	+++ /++++	++++

—, absent; ±, occasionally present; +, minimal; ++, mild; +++, moderate; +++++, marked or severe.

erythematous and painful, but over several days skin changes include color changes, formation of bullae, and cutaneous gangrene. The involved area becomes anesthetic secondary to thrombosis of small blood vessels and destruction of superficial nerves. Anesthesia may develop before the appearance of skin necrosis and is an important clue to the presence of necrotizing fasciitis rather than simple cellulitis.⁸⁶ Subcutaneous gas is often present, and systemic toxicity is common.⁹¹ When the lesion is probed at the bedside or in the operating room, there is no resistance along tissue planes. In type II (also known as hemolytic streptococcal gangrene), group A streptococci are generally isolated alone or in combination with *S. aureus*.⁹² These strains usually produce pyrogenic exotoxin A. Periodically, group C or group G streptococci are causative organisms. Infection usually develops at a site of trauma but may occur in the absence of an obvious portal of entry.⁹¹ The involved area is extremely painful, erythematous, and edematous. Infection spreads widely in deep fascial planes with relative sparing of the overlying skin and therefore may not be recognized. This form of necrotizing fasciitis is present in approximately 50% of cases of streptococcal toxic shock syndrome.⁹² Over several days, the skin becomes dusky and bullae develop. Bullae then rupture and evolve into an area covered by necrotic eschar, often resembling a third-degree burn. Streptococci can usually be cultured from fluid of the early bullae and frequently from blood. Complications include metastatic abscess formation, and the mortality rate from this infection is high.

Fournier's gangrene is a form of necrotizing fasciitis that involves the male perineum, usually the scrotum, but can involve the penis, the perineum, or the abdominal wall. It

is caused by anaerobic streptococci along with other bacteria such as *E. coli*; *S. aureus*; β -hemolytic streptococci; *Proteus* species; a variety of anaerobes; and, on occasion, *Pseudomonas* species.⁹³ The first symptoms are commonly scrotal swelling and pain followed by progressive necrosis of scrotal skin and subcutaneous tissues.⁹³ The patient may appear toxic. Initially the patient may be erroneously diagnosed with an acute abdomen unless the genitalia are examined. Gangrene of the perineum and sometimes the penis may develop. Urgent and aggressive surgery is necessary along with broad-spectrum antibiotics.

CLOSTRIDIAL MYONECROSIS (GAS GANGRENE)

Gas gangrene is a life-threatening infection of skeletal muscle caused by *Clostridium* species. It should be suspected when the Gram stain of drainage reveals gram-positive bacilli in a patient who is critically ill. Penicillin G is the drug of choice with or without clindamycin. Aggressive surgical exploration and débridement is the mainstay of therapy. The role of hyperbaric oxygen therapy in the treatment of clostridial myonecrosis or in the treatment of necrotizing fasciitis remains controversial. If used, it must be used as an adjunct to surgery.⁹⁴

VIBRIO INFECTIONS

Various *Vibrio* species including *Vibrio vulnificus* have caused mild to severe cellulitis in patients who sustained lacerations or puncture wounds when in contact with saltwater in the southeastern United States and the Gulf of Mexico. Septicemia with secondary necrotizing soft tissue infection may

occur after ingestion of raw or undercooked shellfish in immunocompromised hosts, especially those with cirrhosis.⁹⁵ An increased incidence of *Vibrio* infections has been described as a result of flooding after natural disasters. Doxycycline, third-generation cephalosporins, and fluoroquinolones are effective therapies, along with aggressive surgical débridement of necrotic tissue.

COMMUNITY-ACQUIRED MRSA

During the past decade, community-associated MRSA (CA-MRSA) infections among persons without health care-associated risk factors have emerged in several geographic areas and have become endemic in some areas.⁹⁶ Many of these strains carry the staphylococcal cassette chromosome mec type IV element and the gene encoding Panton-Valentine leukocidin, a toxin that promotes tissue destruction.^{97,98} Although most CA-MRSA infections are mild skin and soft tissue infections, severe, life-threatening cases of necrotizing fasciitis, myonecrosis, necrotizing pneumonia, and sepsis have occurred.^{97,98} For patients with invasive infections caused by CA-MRSA, vancomycin and linezolid are appropriate therapeutic options.⁹⁹ CA-MRSA strains are often susceptible to clindamycin, doxycycline, and trimethoprim/sulfamethoxazole.

SERIOUS GASTROINTESTINAL AND INTRA-ABDOMINAL INFECTIONS

BACTEREMIA ASSOCIATED WITH DIARRHEAL ILLNESS

Of the enteric pathogens, *Salmonella* species are most likely to cause bacteremia and serious infection. Enteric fever is usually caused by *Salmonella enterica* serotype typhi and rarely by *Salmonella paratyphi*, *Salmonella choleraesuis*, *Yersinia enterocolitica*, or *Campylobacter fetus*.¹⁰⁰ Features of classic typhoidal fever caused by *S. enterica* include sustained fever, bacteremia, headache, and abdominal pain. Physical findings include “rose spots,” which are 2- to 4-mm discrete, irregular, blanching pink macules that are often seen on the anterior chest; hepatosplenomegaly; and relative bradycardia. Multiorgan system dysfunction can occur as a consequence of metastatic infection or immune complex deposition.¹⁰¹ Intestinal bleeding or perforation may occur as a result of hyperplasia of the lymphoid tissue in the terminal ileum. Diarrhea is seen in less than 50% of cases and only early in the illness. Constipation is a frequent later complaint. The following specimens should be sent for culture: stool, blood, or bone marrow. Serologic findings may provide supportive evidence or may be useful in epidemiologic evaluation.

Therapeutic options include third-generation cephalosporins, fluoroquinolones, and trimethoprim/sulfamethoxazole. Antimicrobial resistance has been reported. Treatment for uncomplicated cases is 12 to 14 days; 30 days of therapy may be necessary for metastatic foci. Metastatic foci are relatively common in the setting of bacteremia. Infection may involve gallbladder, spleen, bone, joints, and the meninges. There is a propensity to infect preexisting intravascular lesions such as atherosclerotic plaques and aneurysms. Sick cell anemia and the presence of an

orthopedic prosthesis are risk factors for osteomyelitis.¹⁰¹ Meningitis tends to occur in young children.¹⁰¹

PERITONITIS

Peritonitis is a localized or general inflammation of the peritoneal cavity that is generally caused by bacteria or fungi but may be caused by a variety of noninfectious agents such as gastric contents, talc, or bile salts. Infective peritonitis has been classified as primary, secondary, or tertiary. Peritonitis is primary when it is not related directly to other intra-abdominal processes.¹⁰² This classification includes spontaneous bacterial peritonitis (SBP), which occurs in patients with underlying ascites from cirrhosis or nephrotic syndrome, and tuberculous peritonitis. Secondary peritonitis most often arises from an enteric source or pelvic focus and includes peritonitis following an acute perforation of the gastrointestinal tract, intestinal necrosis, postoperative peritonitis that may be secondary to an anastomotic leak, and posttraumatic peritonitis following blunt or penetrating abdominal trauma. Intestinal ischemia and frank necrotic bowel may be caused by a variety of processes including malignancies, vascular insufficiency, volvulus, or intussusception.¹⁰² Rupture of an abscess in the pancreas, liver, or spleen or, rarely, rupture of a distended gallbladder can also cause peritonitis. Localized lower abdominal peritonitis can also result from gynecologic infections such as salpingitis and endometritis. Tertiary peritonitis is described as occurring when clinical and systemic signs of peritonitis persist or recur after treatment for secondary peritonitis. A distinct form of device-associated peritonitis is seen in patients undergoing peritoneal dialysis.

Bacterial peritonitis is typically caused by flora of the large intestine including aerobes, with *E. coli* being the most frequent, and anaerobes, of which *Bacteroides fragilis* is the predominant isolate.¹⁰³ Common symptoms include localized or generalized abdominal pain, nausea, and vomiting. Treatment with corticosteroids may mask typical signs and symptoms, delaying the diagnosis. Signs may include abdominal rigidity, distention, fever, and an overall toxic appearance. A rigid abdomen may be seen in the early stages of an acute peritonitis, although it may be absent in a peritonitis that progresses more slowly, such as that caused by tuberculosis, or when sterile bile, pancreatic fluid, or urine leaks into the peritoneal cavity. As intraperitoneal fluid accumulates, abdominal distention and an ileus occur. The WBC count is usually elevated. Bacteremia may occur, and the sepsis syndrome may develop as peritonitis evolves. Aspiration of peritoneal fluid is an essential part of the evaluation for peritonitis. Laparoscopy or laparotomy may be necessary. Studies performed on peritoneal fluid should include a cell count with differential blood cell count, amylase, Gram stain and aerobic and anaerobic culture, acid-fast smear and culture, and fungal smear and culture.

The primary cause of secondary peritonitis should be sought and eliminated if possible. Liver function tests and a serum amylase level may define a source in the liver, gallbladder, or pancreas. A plain film of the abdomen or a chest radiograph may reveal free air under the diaphragm in the case of a ruptured viscus. A CT scan of the abdomen may reveal an underlying intra-abdominal abscess or other focal process. Antibiotic therapy to cover gram-negative bacillary

organisms and anaerobes should be initiated. Options for empiric therapy include combinations such as a third- or fourth-generation cephalosporin or a fluoroquinolone with metronidazole or monotherapy with a β -lactam/ β -lactamase inhibitor combination, a carbapenem, or a glycylicline such as tigecycline.¹⁰⁴⁻¹⁰⁷ The optimal duration of therapy is not well defined, although nonbacteremic patients are generally treated for 7 to 10 days.¹⁰³ Regimens as short as 2 days of treatment may be adequate in uncomplicated situations with adequate surgical source control and in those with penetrating trauma. Bacteremic patients are generally treated for a total of 14 days using a combination of IV followed by oral therapy.

SBP is caused by the translocation of enteric organisms to regional lymph nodes, which produce bacteremia and ultimately seeding of ascitic fluid.¹⁰⁸ Periodically a urinary tract infection may be the source of bacteremia. SBP occurs most commonly in adults with cirrhosis, nephrotic syndrome, or systemic lupus erythematosus.^{108,109} Coliforms are the most common pathogens in adults, accounting for 70% of infections, with *E. coli* being the most common isolate followed by *Klebsiella* species. Gram-positive cocci may be seen in up to 20% of cases and anaerobes in less than 5%. Generally SBP is monomicrobial in contrast to the polymicrobial nature of most other forms of peritonitis. Findings of SBP may be subtle, so a high index of suspicion is necessary. Ascites is almost always present.¹⁰⁸ Fever and abdominal pain are seen in the majority of patients. New onset or worsening of hepatic encephalopathy may be seen. Some patients may have abdominal tenderness or rebound tenderness, but these findings are less frequent than in other forms of peritonitis. The most useful diagnostic test is a paracentesis.¹⁰⁸⁻¹¹⁰ SBP is defined by an ascitic segmented neutrophil count of at least 250 cells/mm³ with or without a positive fluid culture and no obvious intra-abdominal source of infection.^{109,110} The pH of ascitic fluid is low in SBP, whereas that of sterile ascitic fluid is the same as in serum.¹¹⁰ Despite the low sensitivity ($\approx 33\%$), Gram staining of ascitic fluid should be performed. Patients with other infections of the abdomen, such as tuberculous peritonitis, secondary bacterial peritonitis caused by perforation, or peritonitis caused by noninfectious processes including pancreatitis or malignancy, also may show elevated neutrophil counts. Presence of a single organism generally supports the diagnosis of SBP, although there is a variant of SBP caused by traumatic entry into the bowel during paracentesis that may be polymicrobial, and conversely, gram-negative bacillary organisms may occur as sole pathogens in secondary peritonitis. If mixed gram-positive and gram-negative bacteria are seen, an intestinal perforation is the more likely source.¹¹⁰ Peritoneal fluid should be cultured aerobically and anaerobically. Blood cultures should also be performed and are positive in up to 75% of patients with SBP.¹⁰⁹ Other than for symptom relief, a repeat paracentesis is necessary only when the patient fails to have a clinical response or when an unusual organism is isolated. Treatment is usually continued for a total of 7 to 10 days, although some experts have suggested that a 5- to 7-day course of IV therapy may be adequate.^{109,111,112} Most studies show a high mortality rate of 30% to 40% for this syndrome, and after an initial episode of SBP, the probability of recurrence within 1 year is 70%.^{108,111}

INTRA-ABDOMINAL ABSCESS

Considering the presence of a potential intra-abdominal abscess in febrile patients without any obvious cause of fever is important, especially if there is a predisposing condition such as diverticulitis, inflammatory bowel disease, or a history of recent abdominal surgery or abdominal trauma. Intra-abdominal abscess formation may complicate either primary or secondary peritonitis. The processes that typically predispose to intra-abdominal abscess formation are the same as those that cause secondary peritonitis and include perforation, complicated acute cholecystitis, suppurative cholangitis, acute appendicitis, diverticulitis, intestinal malignancy, surgical procedures, blunt or penetrating trauma, or intestinal ischemia from a mesenteric vascular occlusion, an intestinal obstruction, or a volvulus. Most commonly, abscesses are postoperative complications of trauma or of gastrointestinal or biliary surgery.¹¹³ Abscesses can be found anywhere within the abdomen including the retroperitoneal space. Generally their location is in proximity with the original site of contamination, but they may develop at distant sites.¹¹⁴ One example of distal infection is subphrenic abscess, which may be a consequence of a perforated appendix. Symptoms of intra-abdominal abscess may include fever, chills, anorexia, weight loss, and abdominal pain. Unexplained fever may be the only sign of an occult intra-abdominal abscess. An abdominal CT scan is the imaging modality of choice for diagnosis of abdominal abscess. Drainage is essential to establish the diagnosis, obtain microbiology to target antimicrobial therapy, and achieve therapeutic success. This may be accomplished by the insertion of percutaneous catheters, or by laparoscopic or operative drainage.^{113,114} Large abscesses cannot be eradicated by antibiotic therapy alone. Criteria for considering percutaneous drainage include the presence of a well-defined fluid collection and a safe percutaneous route of access.¹¹⁵ Drains should remain in place until drainage volume is minimal, usually less than 10 mL in a 24-hour period.

A repeat CT scan should be performed to demonstrate complete collapse of the abscess cavity.¹¹³ Indications for operative surgical drainage rather than percutaneous drainage include the following situations: (1) Percutaneous drainage cannot be performed safely; (2) percutaneous drainage fails; (3) there are multiple interloop abscesses; (4) there is a coagulopathy; or (5) there is infected pancreatic necrosis. Antibiotic therapy is indicated to treat inflammation in the surrounding tissue and to prevent metastatic infection and sepsis from bacteremia. Antibiotic coverage should be directed at abdominal flora including aerobic and anaerobic organisms even if anaerobes are not isolated.^{103,112,113} Mortality rate with undrained pancreatic, hepatic, or retroperitoneal abscesses is reported to be 45% to 100%.¹¹⁴ An approach to the management of intra-abdominal abscesses is outlined in [Figure 54.3](#).

BILIARY TRACT INFECTIONS

Infections of the biliary tract, including the gallbladder and the common bile duct, are usually associated with obstruction to the flow of bile. The biliary tract of healthy individuals is sterile. In acute cholecystitis, infection of the

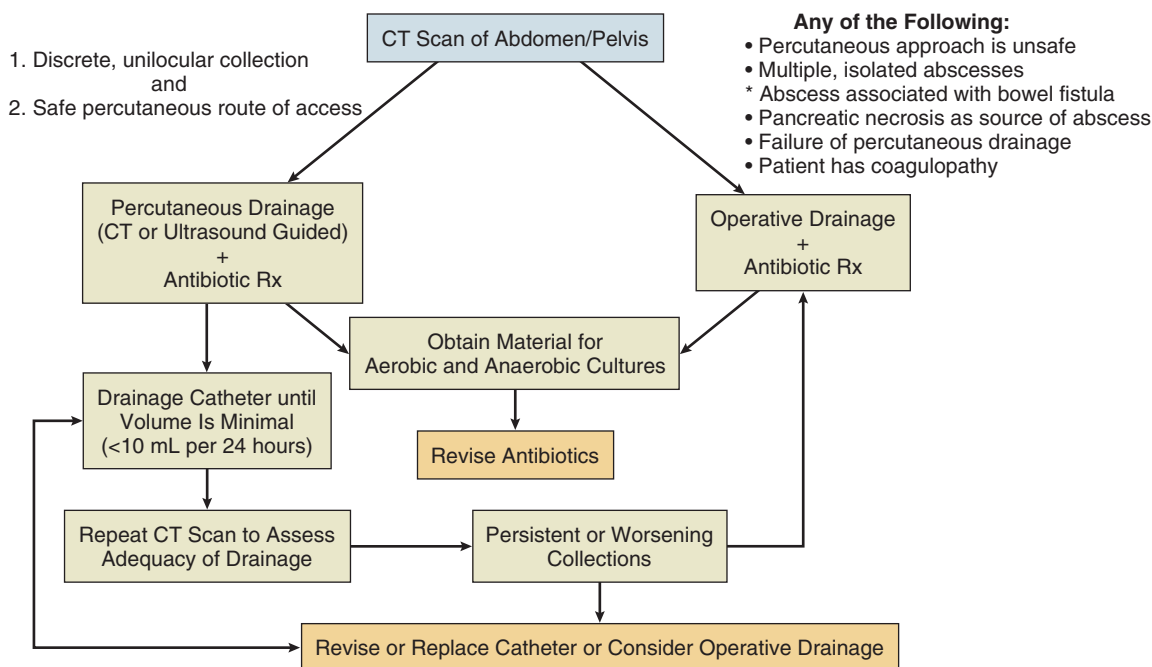

Figure 54.3 Approach to management of intra-abdominal abscesses including indications for consideration of percutaneous versus operative drainage.

gallbladder is most commonly caused by microorganisms that are generally part of the normal intestinal flora.¹¹⁶ Most biliary infections are polymicrobial, and anaerobes are more frequently isolated in the elderly and in those with common bile duct manipulation or prior biliary procedures. The source of bacteria is presumed to be the duodenum.¹¹⁶ Many antibiotics achieve good levels in the bile in the absence of obstruction; however, when obstruction of the hepatic ducts or the common bile duct is present, the levels of such antibiotics are often subtherapeutic. Antibiotic therapy is adjunctive to decompression/drainage, which can be accomplished surgically, percutaneously, or endoscopically via endoscopic retrograde cholangiopancreatography (ERCP). Antibiotics prevent the development of bacteremia, progression of infection, and development of liver abscesses. Cultures of blood and bile should be obtained. Empiric antibiotic therapy should generally be directed at gram-negative bacteria. In patients who are critically ill, the elderly, and those with prior common bile duct and complex biliary procedures, antianaerobic and antienterococcal therapy should also be instituted.

Acute acalculous cholecystitis is an acute inflammation of the gallbladder that occurs in the absence of gallstones. Individuals at risk include debilitated, hospitalized patients such as those who have had major surgical procedures, prolonged intensive care stays, hyperalimentation, or predisposing conditions that result in bile stasis, cholecystoparesis, or gallbladder ischemia.¹¹⁶ The symptoms and findings are similar to those of calculous cholecystitis and include fever, right upper quadrant abdominal pain, nausea, vomiting, leukocytosis, and elevated liver function tests with an obstructive pattern. Diagnostic imaging modalities include ultrasonography, CT scanning, and hepatobiliary iminodiacetic acid (HIDA) scanning. If an open or laparoscopic cholecystectomy cannot be accomplished because of the patient's

underlying condition, then urgent percutaneous cholecystostomy should be performed. In addition, broad-spectrum antibiotics should be instituted.

Acute cholangitis is a serious infection with high morbidity and mortality rates. The most common cause of acute cholangitis is obstruction and subsequent infection associated with stones in the common bile duct, which have usually migrated from the gallbladder. Other causes of biliary tract infection include malignant obstruction of the bile duct secondary to pancreatic cancer, cholangiocarcinoma, cancer of the papilla of Vater, or portahepatic metastases. Periodically biliary strictures, pancreatitis, and infection with the intestinal nematode *Ascaris lumbricoides* can cause obstruction. Bacteria enter the bile duct from the gastrointestinal tract through the bloodstream or lymphatics.¹¹⁷ The most common presenting symptoms are fever, abdominal pain, and jaundice, also known as *Charcot's triad*. Septic shock may occur if treatment is delayed. Blood cultures should be obtained, and ultrasound or CT scanning should be performed. Broad-spectrum antibiotics should be initiated, and biliary decompression accomplished either endoscopically with an endoscopic sphincterotomy, via a percutaneous transhepatic biliary drainage procedure, or by surgical decompression. Endoscopic or percutaneous procedures may be the initial treatment of choice in patients who are seriously ill and at high risk for complications. Elective surgery, which generally includes cholecystectomy and bile duct exploration, can be deferred to a later date when the patient has stabilized.

PANCREATIC INFECTIONS

Although acute pancreatitis is usually a sterile inflammatory process, infectious complications may occur. In addition, a variety of viral infections (rubella; coxsackievirus type B;

mumps; Epstein-Barr virus; CMV; and hepatitis A, B, and C); *Mycoplasma pneumoniae*; and parasites such as *A. lumbricoides* have been implicated as causes of pancreatitis.¹¹⁸ Some patients may develop sterile or infected pancreatic or peripancreatic necrosis, infected pancreatic pseudocysts, or abscess formation as complications of acute pancreatitis.¹¹⁸ Sterile necrosis of either the parenchyma or the duct system usually occurs very early in the clinical course of severe pancreatitis. Risk for infection increases as necrosis becomes more extensive. Of patients with acute pancreatitis, only approximately 5% develop pancreatic infections; however, the highest mortality rate from pancreatitis occurs in these patients.¹¹⁸ The incidence of infection increases over the first few weeks and peaks during the third and fourth weeks. Patients with extensive necrosis, those who are very ill, and those with early infection have the highest mortality rates.¹¹⁸ CT scan with high-dose contrast agent is the most useful modality for predicting who is at risk for the development of infection. Between 40% and 70% of those with more than 30% necrosis seen on CT scan will ultimately become infected.¹¹⁸ If gas bubbles are seen in the region of the pancreas, it should be presumed that infection is present. Clinically, it is extremely difficult to determine whether patients with necrotizing pancreatitis have superimposed infection because sterile pancreatic necrosis may cause leukocytosis and fever even in the absence of infection, and approximately 50% of infected patients may not show early clinical signs of infection. CT-guided fine-needle aspiration of necrotic pancreatic tissue for Gram stain and aerobic and anaerobic culture is a useful procedure to determine the presence of infection.¹¹⁸ The microbiologic picture resembles that of the intestinal flora. *E. coli* is most frequently isolated, followed by *Klebsiella pneumoniae*, *Enterococcus* species, *Pseudomonas* species, and *S. aureus*.¹⁰² Fifteen percent of organisms isolated are intestinal anaerobes. Treatment of pancreatic infection usually involves débridement of infected tissue or drainage of infected pseudocysts or abscesses combined with antimicrobial therapy based on cultures of the infected site. Surgical management often requires multiple staged procedures. Antibiotics that penetrate into pancreatic tissue include the carbapenems, especially imipenem, fluoroquinolones, piperacillin, advanced generation cephalosporins, and metronidazole.¹⁰³

CLOSTRIDIUM DIFFICILE COLITIS

Manifestations of *Clostridium difficile* infection may range from asymptomatic carriage to a fulminant, relapsing, or life-threatening colitis.^{119,120} Antibiotics or chemotherapeutic agents have been associated with alteration of normal bowel flora and growth of *C. difficile*.^{119,120} Diarrhea may develop while a patient is receiving antibiotics or several weeks after completion of a course of antibiotics. Only strains that produce toxins are capable of causing diarrhea or colitis.^{119,120} Common symptoms include fever, which may be either low grade or high, crampy abdominal pain, and diarrhea, which is watery, profuse, and foul smelling. Approximately 50% of patients will have leukocytes in smears of the stool.^{119,120} Leukocytosis is common. The diagnosis is established by assaying the stool for *C. difficile* toxin. Complications of severe disease include electrolyte derangements, dehydration, toxic megacolon, and colonic

perforation. Some patients may have little or no diarrhea but present with toxic megacolon, colonic perforation, peritonitis, or even septic shock without other localizing symptoms. An epidemic strain of *C. difficile*, NAP1/027, has enhanced toxin production and causes outbreaks of illness characterized by increased severity, poorer response to antibiotic therapy, and frequent relapse.¹²¹ Oral metronidazole remains first-line treatment for mild to moderate disease; empiric therapy with oral metronidazole should be started while testing for *C. difficile* toxin is being performed. If patients do not have a favorable response within 3 to 5 days, they should be switched to oral vancomycin. Oral vancomycin should be administered to those with severe infection or unresponsiveness to or intolerance of metronidazole. For patients who are unable to tolerate oral medication, IV metronidazole, vancomycin retention enemas, or vancomycin instillation through a colonic catheter should be administered. Surgery is indicated for complications such as severe toxic megacolon and colonic perforation. A variety of surgical procedures including diverting ileostomy, cecostomy, colostomy, and subtotal colectomy have been performed to manage toxic megacolon. Subtotal colectomy is considered the procedure of choice for the management of fulminant toxic megacolon.

LIFE-THREATENING INFECTIONS OF THE HEAD AND NECK

LUDWIG'S ANGINA, LATERAL PHARYNGEAL SPACE INFECTIONS, AND PERITONSILLAR ABSCESS

Infections arising from the flora of the mouth and posterior pharynx can involve the fascial planes of the neck and have the potential to progress rapidly and cause serious life-threatening illness.^{122,123} In general, these infections are polymicrobial and the microbiology reflects the normal flora of the mouth. These infections spread rapidly through contiguous fascial spaces and it is essential that they be diagnosed and treated expeditiously to prevent serious sequelae such as airway obstruction, hematogenous infection, and mediastinitis. Potentially life-threatening infections of the head and neck may involve three cervical spaces. Fascial planes both separate and connect these areas. The spaces and infectious manifestations are as follows, and representative images are shown in [Figure 54.4](#):

1. The submandibular space may be affected by infection involving the flora of the mouth and tongue. A bilateral cellulitis of the soft tissue, known as *Ludwig's angina*, is the most important type of infection in the submandibular space. Manifestations of this infection include enlargement of the tongue and submandibular swelling. An odontogenic focus is the origin of infection of 70% to 90% of cases.^{123,124}
2. The lateral pharyngeal space consists of an anterior and a posterior compartment divided by the styloid process. The anterior compartment is composed of musculature, and the posterior compartment has nerves and blood vessels. Infection in the anterior compartment causes soft tissue swelling that results in unilateral trismus caused by

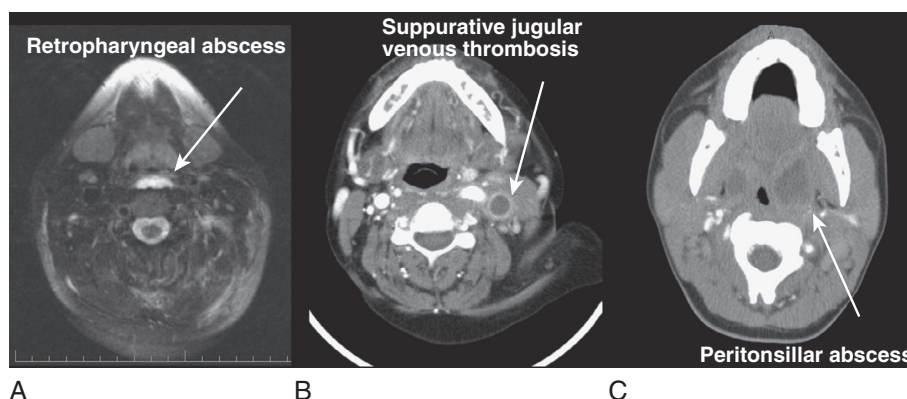

Figure 54.4 Magnetic resonance imaging and computed tomography images showing a variety of life-threatening head and neck infections including retropharyngeal abscess (A), suppurative jugular venous thrombosis (B), and peritonsillar abscess (C). (Images provided by Dr. Joshua Brody, Department of Radiology, the Cooper Health System, Camden, NJ.)

irritation of the internal pterygoid muscle, induration and swelling along the angle of the jaw, bulging of the palatine tonsil into the posterior pharynx, and systemic toxicity. Patients may present with unilateral neck or jaw pain along with ear pain and dysphagia. Pain may worsen when the head is turned because of compression of infected tissue. Dental infection, upper respiratory infection, pharyngitis, and otitis media with mastoiditis may all cause lateral pharyngeal space infection.¹²⁵ The carotid sheath is within the posterior compartment and contains the internal carotid artery, the internal jugular vein, the vagus nerve, cranial nerves IX through XII, and lymph nodes. When infection occurs in this space, patients most commonly present with signs of sepsis without localizing signs at the neck. Generally signs and symptoms are related to complications from involvement of the neurovascular structures. The most common complication is suppurative jugular venous thrombosis. Bacteremia and septic emboli may be seen. The carotid artery may also rupture. The carotid sheath is dense and not easily penetrated, so generally arterial erosion is usually a complication of infections of longer duration (1 to 2 weeks). Intermittent bleeding from the mouth or nose may precede rupture.¹²⁴ Cranial nerve palsies or Horner's syndrome may occur.

3. The retropharyngeal space contains an area that extends from the base of the skull to the diaphragm and hence is a portal for neck infections to extend into the chest. Infections of the retropharyngeal space or prevertebral space may spread as a result of extension through this area. Retropharyngeal space abscesses are relatively uncommon and are most often seen in young children. These abscesses usually result from odontogenic infection, penetrating trauma, or peritonsillar abscess. Peritonsillar abscess, also known as "quinsy," is an unusual complication of acute tonsillitis seen predominantly in adolescents and young adults. Patients usually present with fever, pharyngitis, odynophagia, dysphagia, trismus, drooling, and a muffled voice that has been described as "hot potato" in quality. On examination there is usually swelling of the anterior tonsillar pillars and soft palate. The most common symptoms of retropharyngeal space infection in adults are fever, dysphagia, pharyngeal pain, dyspnea, noisy breathing, and stiff neck. A lateral

radiograph of the neck may reveal prevertebral soft tissue swelling. Any deep neck infection has the potential to spread to the mediastinum via the retropharyngeal space.

Other potential complications of infection of the oral cavity are aspiration pneumonia and lung abscess. Because most of these infections originate from an odontogenic focus, the microbiology reflects polymicrobial oral flora and generally includes *Bacteroides* species, aerobic streptococci, microaerophilic streptococci, peptostreptococci, fusobacteria, *Veillonella* species, and *Actinomyces* species. On occasion, enteric gram-negative bacilli, *P. aeruginosa*, or *S. aureus* may play a role.¹²⁵

Deep neck infections are medical and surgical emergencies. Complications include hematogenous dissemination with sepsis syndrome, airway obstruction, necrotizing pneumonia or empyema, osteomyelitis of the mandible or maxilla, mediastinitis, or intracranial extension and cavernous sinus thrombosis. A contrast CT scan or MRI of the neck is important to help define the anatomy including the vascular structures and to indicate potential need for drainage. Consultation should be obtained from an otolaryngologist. When patients have dyspnea, stridor, or an inability to handle secretions, an artificial airway should be established. Airway obstruction is most likely to occur in infections of the submandibular space. Surgically obtained specimens should be cultured aerobically and anaerobically. For patients with peritonsillar abscess, high-dose IV penicillin is the therapy of choice. Other treatment options include clindamycin or ampicillin-sulbactam. Patients with peritonsillar abscess should undergo incision and drainage to prevent spontaneous rupture, aspiration pneumonia, airway obstruction, or dissection of infection into the lateral retropharyngeal space. Surgical drainage is especially important for infections involving the retropharyngeal and lateral pharyngeal space. Approximately half of cases of Ludwig's angina in the submandibular space can be cured without surgical intervention.¹²⁴

LEMIERRE SYNDROME

Lemierre syndrome (postanginal sepsis) is a fulminant infectious syndrome caused by acute oropharyngeal

infection that is complicated by secondary septic thrombophlebitis of the internal jugular vein. It is usually seen in healthy adolescents or young adults. *Fusobacterium* species are most commonly implicated. Complications include septicemia, pneumonia, empyema, meningitis, brain abscess, and vocal cord paralysis. This infection may complicate a routine case of infectious mononucleosis.¹²⁶ Therapy usually consists of surgical drainage of the focus and broad-spectrum IV antibiotic therapy.

EPIGLOTTITIS

Acute infectious epiglottitis is an inflammatory process of the epiglottis, supraglottis, and surrounding soft tissues.¹²⁷ Since the near disappearance of invasive *H. influenzae* infections in children following universal immunization, acute epiglottitis has become primarily a disease of adults, with an annual incidence of 1 case per 100,000 and peak incidence from ages 40 to 50. Patients present with severe pharyngitis; pain on swallowing; fever; and, less commonly, shortness of breath, hoarseness, and muffled voice. Findings on examination include marked anterior neck tenderness, lymphadenopathy, drooling, and respiratory distress.^{127,128} The standard of diagnosis for suspected epiglottitis in adults is visualization of the epiglottis with indirect laryngoscopy.¹²⁷ Radiography has low sensitivity and specificity. Treatment includes maintenance of an airway; depending on severity and rapidity of onset of symptoms, this may include emergent tracheostomy, elective intubation, or only close observation in an ICU for the mildest cases.¹²⁷ Antibiotics active against the most commonly implicated pathogens, *H. influenzae* and β -hemolytic streptococci, are administered, and corticosteroids are generally recommended.^{127,128} Disease may be more aggressive in HIV-infected or other immunocompromised individuals.

MEDIASTINITIS

Acute mediastinitis is an infection of mediastinal structures that can develop from direct extension of pharyngeal and neck infections (descending necrotizing mediastinitis), from esophageal trauma or rupture, or as a complication of cardiothoracic surgical procedures.¹²⁹ Descending necrotizing mediastinitis and mediastinitis from esophageal procedures have both become uncommon, and most cases are seen as complications of cardiothoracic surgery procedures or from trauma.^{129,130} Symptoms of mediastinitis may initially be mild, but as disease progresses, patients will develop chest pain; dysphagia; and respiratory distress, as well as fever, tachycardia, crepitus, and localized swelling. Sepsis is common. Patients with postcardiothoracic mediastinitis will generally have evidence of local or deep sternal wound infection. Leukocytosis is typical. Plain films may show mediastinal widening; mediastinal air-fluid levels; and subcutaneous, mediastinal, or pericardial air. CT is more sensitive than plain radiographs for diagnosis; contrast esophagography with water-soluble contrast is the optimal study for esophageal perforation.¹²⁹

Treatment of infection related to descending neck infection or esophageal perforation requires broad-spectrum antibiotics directed at oropharyngeal flora including streptococci, oral anaerobes, and gram-negative bacilli

in addition to surgical intervention.¹²⁹ Mediastinitis following cardiothoracic surgery is most commonly caused by staphylococci, but a large variety of other gram-positive and gram-negative organisms have been implicated. Treatment requires surgical drainage and débridement along with antibiotic therapy.¹³⁰

SERIOUS VECTOR-BORNE INFECTIONS

ROCKY MOUNTAIN SPOTTED FEVER

Tick-borne rickettsial diseases cause severe illness and death in otherwise healthy individuals. Although the various rickettsial diseases may have distinct epidemiologic and etiologic differences, they are clinically similar.¹³¹ RMSF is caused by *Rickettsia rickettsii*, which is a gram-negative, obligate, intracellular bacterium. Infection is transmitted to humans by a variety of ticks but most frequently by the dog tick, *Dermacentor variabilis*. The incidence is greatest in the southeastern and south central United States. The vast majority of cases occur from April to September. Reported risks for infection include living in wooded areas and exposure to dogs. *R. rickettsii* infects endothelial cells, resulting in vasculitis, which leads to the characteristic rash and involvement of the lungs, brain, and other organs.¹³¹⁻¹³⁴ Following an incubation period of 3 to 12 days, patients frequently present with fever, rash, and evidence or history of a tick bite, although 30% to 40% of patients do not recall a tick bite.¹³¹ Other symptoms include chills; myalgias; nausea; vomiting; abdominal pain that may be severe enough to mimic an acute abdomen; diarrhea; headache; photophobia; mental status changes; conjunctival injection; and, periodically, cough or arrhythmias secondary to myocarditis. The rash is classically an erythematous macular rash that appears initially on the ankles/soles and wrists/palms and spreads centripetally to the arms, legs, trunk, neck, and face.¹³²⁻¹³⁴ The lesions evolve to become petechial. The rash typically appears after 2 to 6 days of illness. Although rash is the hallmark of this illness, up to 20% of patients are “spotless” or have an atypical rash at presentation.¹³⁵ The most characteristic laboratory abnormality is thrombocytopenia. The WBC count is usually normal but more than two thirds of cases have increased band forms. The creatine phosphokinase level may be elevated, as may transaminases and bilirubin.¹³¹ The chest radiograph may reveal infiltrates consistent with pneumonitis or acute respiratory distress syndrome (ARDS). RMSF is frequently a severe illness. Serious complications, in addition to ARDS, include renal failure, disseminated intravascular coagulopathy (DIC), hemophagocytic syndrome, meningoencephalitis, and gangrene.¹³¹

Rickettsial infections may be difficult to diagnose. The best way to establish the diagnosis of RMSF in patients with a rash is by obtaining a skin biopsy for immunohistochemical or direct immunofluorescent staining. This test has a sensitivity of 70% and specificity of 100%.¹³² PCR can also be performed on tissue specimens.¹³¹ However, both immunohistochemical staining and RMFS PCR may not be readily available in many institutions. Serologic testing by indirect immunofluorescence or enzyme-linked immunosorbent assay (ELISA) may also be performed. Empiric treatment

with doxycycline should be instituted for suspected RMSF before laboratory confirmation of a diagnosis. Distinguishing RMSF from meningococcemia is especially important. Gastrointestinal symptoms, a pulse-temperature disparity, periorbital edema, edema of the extremities, conjunctival injection, hepatosplenomegaly, and elevated serum transaminases are more likely in RMSF. If there is any doubt as to which infection is present, treatment for both should be instituted empirically.

EHRlichIOSES AND ANAPLASMOSIS

Illnesses that cause fever and rash are listed in [Box 54.3](#). Other serious rickettsial diseases include ehrlichioses and anaplasmosis, caused by *Ehrlichia chaffeensis*, *E. ewingii*, and *Anaplasma phagocytophilum*, respectively.¹³¹ They have a similar presentation, but rash is much less commonly seen than in RMSF. These infections are transmitted by ticks and are distributed across the United States and Europe. All are intracellular pathogens that infect leukocytes. Common laboratory abnormalities include leukopenia, relative lymphopenia, presence of atypical lymphocytes, eosinopenia, and thrombocytopenia.¹³⁶ Anemia and renal involvement are rare. PCR of serum is now the rapid diagnostic test of choice. Blood smear microscopy might reveal the presence of morulae in infected leukocytes, which is highly suggestive of anaplasmosis or, less commonly, ehrlichiosis.¹³¹ Serologic results can also be diagnostic. Complications include ARDS, bleeding, rhabdomyolysis, and myocarditis.¹³⁶

MALARIA

Malaria is a protozoan infection transmitted by female anopheline mosquitoes. The severity of malaria infection depends on a variety of factors including host immunity and

age and the species of malaria. Of the four main human pathogens, *Plasmodium falciparum* causes the most serious infection. Chloroquine-resistant *P. falciparum* has spread through many parts of the world. The incubation period of *P. falciparum* is approximately 12 days. It parasitizes all ages of red blood cells and causes the highest degree of parasitemia of any of the species.¹³⁷ *P. falciparum* has worldwide distribution and causes a severe illness frequently termed *blackwater fever*. Common symptoms and signs include fever, chills, headache, myalgia, arthralgia, and hepatosplenomegaly. Other symptoms include jaundice, vomiting, diarrhea, and nonproductive cough.¹³⁷ Severe malaria is a multisystem illness with a mortality rate of up to 25% in the nonimmune, untreated patient.¹³⁷ Defining criteria for severe malaria include (1) severe normocytic anemia, (2) renal failure, (3) pulmonary edema, (4) hypoglycemia, (5) shock, (6) DIC, (7) metabolic acidosis, and (8) cerebral involvement with coma or generalized seizures. Other signs or symptoms frequently present in severe disease include altered mental status, prostration, jaundice, and high-grade fever.^{137,138} Additional laboratory features include thrombocytopenia, elevated transaminases, hyperbilirubinemia, evidence of coagulopathy, elevated blood urea nitrogen (BUN) and creatinine levels, and macroscopic hemoglobinuria. Levels of parasitemia are often high. Patients may develop pulmonary edema, or pulmonary edema may occur after successful treatment of parasitemia. ARDS or secondary infection with bacterial pneumonia may also occur.

The differential diagnosis is broad and includes bacterial sepsis, meningitis, rickettsial infections, pneumonia, viral hemorrhagic fever, leptospirosis, severe influenza, meningococcemia, typhoid fever, and viral hepatitis. The diagnostic test of choice is the thick/thin peripheral Giemsa-stained blood smear, which confirms the diagnosis. Rapid diagnostic tests are becoming increasingly useful. However, patients from an endemic area may occasionally present with another serious illness that may be erroneously attributed to malaria because of incidental parasitemia. Treatment for severe malaria regardless of species consists of IV quinine (not available in the United States) or IV quinidine combined with IV doxycycline or IV clindamycin.^{139,140} When using quinidine, continuous cardiac monitoring should be performed. IV artesunate is available as an investigational new drug through the CDC for those with severe malaria who are unable to obtain IV quinidine or who are intolerant to it, have a contraindication, or have failed therapy. IV therapy should be continued until the parasite density is less than 1% and oral therapy can be tolerated. Adjunctive therapy for severe malaria may include exchange transfusion, although this is controversial.¹³⁹ In addition, broad-spectrum antibiotics for bacterial sepsis and pneumonia should be given if there is concern for secondary bacterial infection.

DENGUE

Hemorrhagic fever is caused by a variety of viruses, and the hallmark is bleeding. Generally dengue has a geographic endemicity, being seen predominantly in Africa, South America, and Asia. Dengue is transmitted by mosquitoes and has no other reservoir except humans. It is now endemic in at least 112 countries worldwide including many parts of

Box 54.3 Differential Diagnosis of Fever with Maculopapular or Petechial Rash

- Rocky Mountain spotted fever
- Meningococcal disease
- Enteroviral infection (echovirus and coxsackievirus)
- Human herpesvirus 6 infection (roseola)
- Human parvovirus B19 infection (fifth disease)
- Epstein-Barr virus infection
- Disseminated gonococcal infection
- Murine typhus
- Ehrlichioses
- Group A streptococcal pharyngitis
- Mycoplasma pneumoniae* Infection
- Leptospirosis
- Secondary syphilis
- Kawasaki disease
- Thrombotic thrombocytopenic purpura (TTP)
- Drug reactions
- Immune complex-mediated illness
- Toxic shock syndrome
- Erythema multiforme
- Stevens-Johnson syndrome

the Caribbean, Mexico, Puerto Rico, and Central America and has recently reemerged in the United States in the Florida Keys and along the Mexican border.¹⁴¹⁻¹⁴⁴ In many areas the mosquito vector is *Aedes aegypti*. This mosquito species has adapted to man-made conditions, and therefore urban transmission is frequent. The virus has four serotypes, each with a number of genotypes.¹⁴³ Dengue is generally divided into four clinical syndromes: a mild influenza-like illness; classic dengue (characterized by fever, retro-orbital headache, severe bone pain and myalgia, maculopapular rash, and nausea and vomiting); dengue hemorrhagic fever (DHF); and dengue shock syndrome (DSS).¹⁴¹ DHF or DSS may manifest after a few days of typical dengue symptoms, and classically symptoms start as the temperature normalizes.¹⁴⁴ Those with DHF have bleeding, petechiae, ascites, pleural effusion, and sometimes encephalopathy. Laboratory features include hemoconcentration, leukopenia, elevated transaminases, and thrombocytopenia.¹⁴⁴ The differential diagnosis includes many of the infectious entities also in the differential diagnosis of malaria. Noninfectious illnesses in the differential diagnosis include hemolytic uremic syndrome and thrombotic thrombocytopenic purpura. Diagnosis is established serologically, and treatment is supportive.¹⁴³

SEVERE VIRAL INFECTIONS

HANTAVIRUS PULMONARY SYNDROME

Acute infections caused by species of hantavirus are transmitted to humans from rodents and are characterized by nephritis and hemorrhage or by a syndrome of acute noncardiogenic pulmonary edema.¹⁴⁵ Four hantaviruses are associated with hantavirus pulmonary syndrome (HPS). This syndrome was first recognized in the southwestern United States. Rodents, especially deer mice, are the host. Transmission to humans occurs by inhalation of aerosols of rodent urine or feces. Initial symptoms of HPS resemble those of influenza and consist of fever, myalgia, headache, and gastrointestinal symptoms. Two to 15 days later, acute noncardiogenic pulmonary edema and shock develop.¹⁴⁶⁻¹⁴⁸ Laboratory findings at this stage include leukocytosis, hemoconcentration, and thrombocytopenia. Chest radiographic findings include increased vascular markings consistent with pulmonary edema, bilateral infiltrates, and pleural effusions.¹⁴⁹ Treatment is supportive and consists of ventilator support and treatment of shock. This syndrome has a high mortality rate of 50% to 70%, but those who survive improve rapidly after 5 to 7 days and often have complete recovery within 2 to 3 weeks.

INFLUENZA

Influenza results from infection with influenza A or B virus. Infection occurs in yearly epidemics, typically during the winter in temperate climates, with occasional worldwide epidemics referred to as *pandemics*, which occur when there is antigenic shift (a major antigenic change resulting in a new subtype of influenza A).¹⁵⁰ These viruses are spread from person to person primarily through coughing and sneezing.¹⁵¹ Onset of symptoms is abrupt and occurs after an

incubation period of a day or two.¹⁵² Symptoms include fever, chills, headache, myalgia, sore throat, and malaise.¹⁵³ Respiratory symptoms, especially a dry cough, are usually present. As systemic signs and symptoms decrease, respiratory complaints become more prominent. Of these, cough is the most frequent and may persist 1 to 2 weeks after fever resolves. Leukocytosis is common early in the illness, and mild leukopenia may be observed later. Most cases are not associated with any significant complications, but when complications do occur, pulmonary complications are the most frequent. Two types of pulmonary complications are recognized: primary influenza viral pneumonia and secondary bacterial pneumonia.¹⁵⁴ Primary influenza viral pneumonia occurs mainly in individuals with cardiovascular disease or in pregnant women. Rapid progression of fever, cough, dyspnea, and hypoxemia usually occurs. Chest radiographs reveal bilateral findings consistent with pulmonary edema. Patients may develop ARDS. Culture of the sputum fails to reveal significant bacteria, whereas molecular diagnostic tests and viral cultures will demonstrate influenza virus. Severe influenza viral pneumonia requires intensive monitoring and support. Mortality rate is high.

Secondary bacterial pneumonia is more common than primary viral pneumonia. It occurs most often in the elderly or those with preexisting pulmonary disease. Following a classic influenza syndrome and a period of improvement of a few days, there is recrudescence of fever and cough accompanied by sputum production and consolidation on chest radiograph. Gram stain and culture of sputum most often demonstrate *S. pneumoniae*, *H. influenzae*, or *S. aureus*. Other rare complications of influenza include Reye syndrome, which is an often fatal CNS and hepatic complication, myositis, transverse myelitis, myocarditis, and pericarditis.¹⁵⁵ Influenza virus is readily isolated from nasal or throat specimens, sputum, or tracheal secretions in the first 2 or 3 days of illness. The neuraminidase inhibitors, inhaled zanamivir and oral oseltamivir, are active against influenza A and B viruses and are effective in treating acute influenza if started early in the illness.¹⁵⁰ Secondary bacterial pneumonia should be treated with antibiotics. A pandemic with H1N1 occurred in 2009 and public health readiness continues for the next pandemic.¹⁵⁶ Respiratory syncytial virus is emerging as an important cause of serious illness in the elderly and high-risk adults with clinical manifestations, length of hospital stay, use of ICU, and mortality rates similar to influenza.¹⁵⁷

POTENTIAL AGENTS OF BIOTERRORISM

Potential agents of bioterrorism include rare infections that may occur sporadically in specific epidemiologic settings, such as anthrax, as well as diseases considered eradicated, such as smallpox. Features of these illnesses are their potential to cause illness and death, the potential for large-scale dissemination, their ability to cause public disruption, and the requirement for specific public health interventions in the setting of an outbreak. Illness is generally severe, and infected patients are likely to require admission to critical care units. Recognition of these syndromes by clinicians is crucial to triggering the appropriate medical, public health, and governmental response.

ANTHRAX

Bacillus anthracis, the causative agent of anthrax, is an aerobic, gram-positive, sporulating bacillus. When human infection occurs, spores germinate in blood and tissue. Human infection can be of three types: (1) cutaneous, (2) inhalational, and (3) gastrointestinal.¹⁵⁸ Cutaneous is the most common and characteristically appears as a painless papule that evolves to a vesicular stage and then to a depressed black eschar surrounded by a ring of vesicles. Untreated, it carries a mortality rate of approximately 20%.¹⁵⁸

The inhalational form is the form most likely to be encountered in the critical care setting. After an incubation period of generally 1 to 7 days but potentially up to 60 days, patients present with fever, malaise, dry cough, and an influenza-like illness. Progression to severe respiratory distress and septic shock occurs. The hallmark of this infection is a hemorrhagic mediastinitis.^{158,159} Mortality rate has been as high as 85%. In virtually all cases, chest radiographs are abnormal and show either a widened mediastinum or pleural effusions. CT scan is particularly sensitive in detecting mediastinal changes.¹⁶⁰ Blood cultures are positive in 70% of cases. Clinical suspicion should be raised by the sudden appearance of multiple cases of severe influenza-like illness with a fulminant course and high mortality rates. The diagnosis is generally established by culturing the organism from blood, CSF, pleural fluid, or vesicular fluid; by PCR; or by biopsy. Therapy is initially empiric and consists of the combination of ciprofloxacin or doxycycline plus clindamycin and rifampin.^{158,159}

SMALLPOX

Smallpox is caused by the variola virus. This serious infection is highly contagious and fatal in about 30% of cases. Two major clinical forms exist, with the most common being variola major. This is a severe form with extensive rash and high fever. After an incubation period of 12 to 14 days, patients develop high fever, malaise, headache, myalgias, and vomiting. The rash appears initially as small intraoral spots and within 24 hours develops on the face, then spreads to the legs, feet, arms, and hands.¹⁶¹ The rash appears as papules, which are filled with a thick, opaque fluid and have a depressed center. They evolve into pustules, which are raised, round, and firm to the touch. The differential diagnosis includes varicella. Treatment is supportive. The antiviral agent cidofovir may have activity.¹⁶²

PLAGUE

The causative agent of plague is *Yersinia pestis*, an aerobic gram-negative bacillus. The three clinical forms are (1) bubonic, (2) pneumonic, and (3) septicemic.^{163,164} Pneumonic plague is transmitted person to person through inhalation of contaminated aerosols and is highly contagious. After an incubation period of 2 to 3 days, patients develop fever, chills, headache, hemoptysis, dyspnea, stridor, cyanosis, respiratory failure, circulatory collapse, and bleeding.^{163,164} Diagnosis is based on clinical suspicion and confirmed by culture. Treatment is with streptomycin and doxycycline.^{163,164}

TULAREMIA

Tularemia is caused by *Francisella tularensis*, which is a gram-negative coccobacillus. Types of infection include ulceroglandular, typhoidal, and pneumonic. If there were to be an intentional release of this agent, infection would likely occur via the aerosol route.^{165,166} Symptoms include cough, substernal pain, abdominal pain, prostration, fever, chills, and headache. Diagnosis is established by culture onto special media or by serologic testing. Treatment is with streptomycin.

VIRAL HEMORRHAGIC FEVERS

Viral hemorrhagic fevers are caused by several different families of viruses. Symptoms generally include fever, myalgia, hemorrhage, shock, coma, seizures, and possibly renal failure. The diagnosis is established by viral isolation or serologically. Treatment involves supportive care. The antiviral agent ribavirin may have a role in treatment.¹⁶⁷

KEY POINTS

- Of patients with bacterial meningitis, 95% will have at least two of the following symptoms: fever, headache, stiff neck, and altered sensorium.
- Morbidity and mortality rates of bacterial meningitis are decreased with prompt administration of antibiotics.
- When dexamethasone is administered as adjunctive therapy for bacterial meningitis, it should be given prior to or concurrent with initial antibiotic doses.
- The standard for diagnosis of herpes encephalitis is PCR of CSF, and treatment for suspected herpes encephalitis should be continued until PCR results are back.
- *S. aureus* has become the most common cause of bacterial endocarditis, and *S. aureus* endocarditis is associated with a high risk of complications and high mortality rates.
- Major indications for surgery in acute endocarditis include congestive heart failure, persistent bacteremia and sepsis, ongoing emboli on appropriate antibiotic therapy, and local valvular complications such as dehiscence and perivalvular abscess.
- Staphylococcal and streptococcal toxic shock syndromes are mediated by systemic effects of bacterial exotoxins that trigger massive release of cytokines.
- Necrotizing fasciitis, although uncommon, is a severe infection that causes necrosis of subcutaneous tissue and fascia and requires prompt identification and therapy to minimize morbidity and mortality rates.
- CA-MRSA is an emerging pathogen that can cause life-threatening illness including necrotizing skin infections, pneumonia, and sepsis.

KEY POINTS (Continued)

- Empiric antibiotic therapy for bacterial peritonitis should be directed at gram-negative bacillary organisms and anaerobes.
- The presence of an intra-abdominal abscess should be entertained in febrile patients without any obvious cause of fever or in the seriously ill patient who is on corticosteroid therapy.
- An epidemic strain of *C. difficile* has enhanced toxin production and causes increased severity of illness, poorer response to therapy, and frequent relapse.
- Serious infections of the head and neck are polymicrobial and most frequently have an odontogenic source.
- Serious complications of influenza include primary influenza viral pneumonia, bacterial pneumonia, Reye syndrome, and myocarditis/pericarditis.

Renal Replacement Therapy

PROGNOSIS AND OUTCOMES

DEFINITION

The primary function of the kidneys is the excretion of metabolic waste products and the maintenance of the composition of body fluids through regulation of water, electrolyte, and acid-base excretion. Acute kidney injury (AKI) describes a sudden decrease in glomerular filtration rate (GFR), resulting in the retention of metabolic waste products and dysregulation of fluid, electrolyte, and acid-base homeostasis.¹⁻³ AKI, however, does not represent a discrete disease. Rather, AKI is a heterogeneous spectrum that includes hemodynamic perturbations that disrupt normal renal perfusion and decrease GFR without causing overt parenchymal injury; partial or complete obstruction to urine flow; and acute parenchymal injury resulting in glomerular, interstitial, tubular, or vascular dysfunction. Although all forms of AKI can occur in those who are critically ill, the most common causes in this population include hemodynamically mediated prerenal dysfunction and *acute tubular necrosis* (ATN) arising as a result of ischemia-reperfusion injury, nephrotoxin exposure, or sepsis.

The term *acute kidney injury* has largely replaced the older terminology of *acute renal failure* (ARF).³⁻⁶ Implicit in this older terminology was a focus on the most severe presentations of acute kidney dysfunction, generally characterized by overt organ failure. The term *AKI* attempts to broaden the focus to include less severe episodes that, although not resulting in overt organ failure, are associated with increased risks of morbidity and mortality, particularly in the critically ill. However, the use of the term *injury* may incorrectly connote the presence of parenchymal organ damage, which may be absent in a number of forms of AKI, particularly in hemodynamically mediated prerenal states and acute obstructive uropathy. In this chapter, the term AKI will be used to describe the entire spectrum of the syndrome, and the term ARF will be restricted to severe organ failure requiring renal replacement therapy. Often, the terms ATN and AKI have been used interchangeably; although ATN is the most common form of intrinsic AKI, particularly in critically ill patients, the terms are not synonymous, because ATN represents only one of the multiple forms of AKI.

The cardinal manifestation of AKI is the retention of metabolic waste products, most notably creatinine and urea.^{1,2} Decreased urine output may also be a manifestation of AKI; however, the urine output in AKI can be highly variable, ranging from virtual anuria (<100 mL/day) to

 Additional online-only material indicated by icon.

polyuria (>3 L/day).¹ In addition, transient oliguria (urine volume <400 mL/day) may occur in the absence of decreased kidney function in patients with intravascular volume depletion as the physiologic response to volume depletion due to an increase in tubular salt in water reabsorption.⁷ In contrast, persistent oliguria despite adequate volume resuscitation is virtually always a manifestation of AKI.⁷ Although the presence of oliguria complicates management, increasing the risk of volume overload, hyperkalemia, and other electrolyte disturbances, and is associated with a greater mortality risk, therapeutic interventions to augment urine output have not been shown to improve outcomes.

A wide array of operational definitions have been used to define AKI based primarily on relative or absolute changes in serum creatinine concentration.¹⁴ The first attempt at developing a consensus definition was undertaken by the Acute Dialysis Quality Initiative in 2002¹⁵; the resultant RIFLE criteria consisted of three strata (“Risk,” “Injury,” and “Failure”) based on the magnitude of increase in serum creatinine and the duration of oliguria as well as two outcome stages (“Loss” of kidney function and “End-Stage” kidney disease) (Table 55.1). In the RIFLE criteria, the “Risk,” “Injury,” and “Failure” strata were defined based on an increase in serum creatinine developing over 7 days of 50%, 100%, or 200%, respectively, relative to baseline or oliguria, defined as a urine output of less than 0.5 mL/kg/hour for more than 6 hours (“Risk”) or 12 hours (“Injury”) or a urine output of less than 0.3 mL/kg/hour for more than 24 hours or anuria for more than 12 hours (“Failure”). These three strata were proposed as providing increasing

specificity, although decreasing sensitivity, for the diagnosis of AKI. The outcome criteria were defined based on continued need for renal replacement therapy for more than 4 weeks (“Loss”) or more than 3 months (“Failure”). The RIFLE criteria were subsequently modified by the Acute Kidney Injury Network (AKIN) with the addition of an absolute increase in serum creatinine of more than 0.3 mg/dL to the definition of AKI, a decrease in the time frame for the increase in serum creatinine from 7 days to no more than 48 hours, and by dropping the two outcome criteria.^{4,5} More recently, the Kidney Disease Improving Global Outcomes (KDIGO) Clinical Practice Guideline for Acute Kidney Injury harmonized the RIFLE and AKIN definitions, maintaining the three stages, but specifying that the 0.3-mg/dL increase in serum creatinine was to have developed over no more than 48 hours but that the greater than 50% increase could occur over up to 7 days (see Table 55.1).³

The development of a standardized operational definition and staging system has introduced a degree of uniformity to clinical trials of AKI; however, their utility in the bedside care of patients remains uncertain. The definitions have increased recognition of less severe episodes of AKI, but data are lacking to demonstrate that use of these criteria can meaningfully guide patient care. Several important shortcomings to these definitions and staging criteria must also be recognized. First, as previously discussed, there is poor correlation between change in serum creatinine and actual GFR in the non-steady-state conditions that are present in AKI. Thus, there may be discordance between the level of GFR and the AKI staging. For example, within

Table 55.1 RIFLE, AKIN, and KDIGO Definitions and Staging of Acute Kidney Injury

	Serum Creatinine Criteria			Urine Output Criteria
	RIFLE	AKIN	KDIGO	
Definition	Increase in serum creatinine of >50% developing over <7 days	Increase in serum creatinine of 0.3 mg/dL or >50% developing over <48 hours	Increase in serum creatinine of 0.3 mg/dL developing over 48 hours or >50% developing over 7 days	Urine output of <0.5 mg/kg/hour for >6 hours
Staging				
RIFLE–Risk AKIN/ KDIGO Stage 1	Increase in serum creatinine of >50%	Increase in serum creatinine of 0.3 mg/dL or >50%	Increase in serum creatinine of 0.3 mg/dL or >50%	Urine output of <0.5 mg/kg/hour for >6 hours
RIFLE–Injury AKIN/ KDIGO Stage 2	Increase in serum creatinine of >100%	Increase in serum creatinine of >100%	Increase in serum creatinine of >100%	Urine output of <0.5 mg/kg/hour for >12 hours

the first 24 hours following an acute ischemic insult the GFR may be essentially zero, but there will have been insufficient time for the serum creatinine to rise beyond the 50% threshold for stage 1 disease; by the time the serum creatinine has increased to a level to fulfill the criteria for stage 3 AKI, the GFR may already be improving. Second, the definition of AKI using the serum creatinine criteria requires a valid referent baseline serum creatinine measurement, which is often unavailable. Third, the reliance of the staging systems on relative changes in serum creatinine makes the staging system highly dependent on baseline kidney function. Because the maximal daily rise in serum creatinine is dependent upon relative muscle mass and not on kidney function, the time to progress from stage 1 to stage 2 or from stage 2 to stage 3 will be longer for a patient with a baseline serum creatinine of 1.4 mg/dL than for a similar patient with a baseline serum creatinine of 0.7 mg/dL. Fourth, concordance between the serum creatinine and urine output criteria has not been established and urine output may be highly dependent upon other factors, including intravascular volume resuscitation and diuretic administration. Fifth, the staging system is focused entirely on the magnitude of the peak excursion in serum creatinine and not on duration of AKI, which may be an independent predictor of outcomes. Sixth, although studies validating these criteria have demonstrated that the AKI stage correlates with increasing mortality risk, it is not clear that mortality risk is the appropriate measure of disease severity. Finally, these classification systems treat AKI as a single disease rather than as a widely heterogeneous syndrome and do not take into consideration the underlying cause of AKI. Despite these shortcomings, the use of these standardized definitions and staging systems has enhanced comparisons across epidemiologic studies and facilitated the design of clinical trials.

EPIDEMIOLOGY

Estimates of the incidence of AKI are highly dependent on both the precise definition employed and the characteristics of the patient population studied. Many of the epidemiologic studies that have been published either preceded the development of the standardized definitions just described¹⁶⁻²⁴ or have utilized administrative data that do not correlate with these definitions.²⁵⁻²⁸ In addition, there are important differences in the distribution of the different types of AKI among patients who develop AKI prior to hospitalization, on general medical-surgical wards, or in the intensive care unit. As a result, published estimates of the incidence of AKI in hospitalized patients have ranged from as high as 44%, using a 0.3-mg/dL change in serum creatinine as the definition to less than 1% when the definition was based on an increase in serum creatinine of more than 2 mg/L, with most estimates of the incidence of AKI ranging from 3% to 7% of the overall hospital population and 10% to 35% of critically ill patients, and 5% to 6% of the ICU (intensive care unit) population having AKI severe enough to require renal replacement therapy.¹⁶⁻²⁴

The incidence of AKI has increased substantially over the past several decades. In an analysis of data from the National Hospital Discharge Survey in the United States conducted by the Centers for Disease Control and Prevention, the

incidence of AKI among hospitalized patients increased from 18 per 100,000 population in 1980 to 365 per 100,000 population in 2005 with similar trends present in analyses of data from the U.S. National Inpatient Sample and a 5% sample of hospitalized Medicare beneficiaries.²⁸ These data need to be interpreted with some caution; however, administrative coding for AKI is incomplete, capturing only 20% to 30% of all episodes, and trends over time may be subject to bias from changes in administrative coding practices.²⁹ However, similar trends were observed in an analysis of administrative and clinical data from Kaiser Permanente of Northern California, an integrated health care delivery system.³⁰ Using laboratory creatinine data to confirm the diagnosis of AKI, the incidence of AKI not requiring renal replacement therapy increased from 323 to 522 cases per 100,000 person-years between 1996 and 2003; over the same time period, the incidence of AKI requiring renal replacement therapy increased from 19.5 to 29.5 cases per 100,000 person-years. Epidemiologic studies have consistently found that AKI is more prevalent in men and in African Americans and increases in incidence with increasing age.^{25,26} Increasing risk of AKI is also associated with severity of baseline chronic kidney disease (CKD). In the aforementioned study from Kaiser Permanente of Northern California, the risk of developing AKI requiring dialysis was approximately double in patients with a baseline estimated GFR between 45 and 60 mL/minute/1.73 m² as compared to patients with an estimated GFR greater than 60 mL/minute/1.73 m², with the risk increasing to more than 40-fold among patients with a premorbid estimated GFR less than 15 mL/minute/1.73 m².³¹ Other identified independent risk factors for the development of AKI include diabetes mellitus, hypertension, and the presence of proteinuria.^{31,32}

Although AKI is common in critically ill patients, robust epidemiologic data are lacking as the majority of published studies represent the experience at single centers or limited numbers of ICUs.^{19-23,33,34} In addition to varying criteria used to define AKI, the incidence of AKI is also highly dependent upon the characteristics of the ICU population. As shown in Figure 55.1, the incidence of AKI is lower in the cardiac care unit and in patients after coronary artery bypass grafting, being 5% to 10%,^{35,36} as compared to patients with severe trauma,³⁷ burns,³⁸ and following liver and allogeneic bone marrow transplant, in whom AKI occurs in 20% to 40%.³⁹ The patterns of AKI in the ICU differ from those seen in the general hospital population (Table 55.2). Patients with ICU-associated AKI are younger, are more likely to be male, are more likely to have acute tubular necrosis as compared to prerenal AKI or obstructive disease, are more likely to have AKI in association with multisystem organ failure as opposed to isolated AKI, are more likely to require renal replacement therapy, and have markedly higher mortality rates.¹⁹ Sepsis is the most common predisposing condition for the development of AKI in critically ill patients, contributing to the development of AKI in as many as half of all cases.^{19,21,22,24} Other conditions associated with the development of AKI in ICU patients include major surgery, cardiogenic shock, hypovolemia, medication-associated toxicity, and advanced liver disease (Table 55.3).^{19,21,22,24} Two distinct patterns of ICU-associated AKI have been described: early-onset AKI is present on ICU admission or within the first 48 hours of ICU stay, and

Hypovolemia	15-30
Liver failure	5-10

late-onset AKI develops after more than 48 hours of ICU care.²³ Delayed-onset AKI is more likely to be due to post-ischemic or sepsis-associated AKI and is associated with higher mortality rates.

PATHOGENESIS

AKI can be divided into three broad etiologic categories: prerenal AKI, intrinsic AKI, and postrenal (obstructive

AKI). Prerenal states (Box 55.1) are characterized by effective hypoperfusion of the kidneys leading to a decrease in GFR in the absence of overt parenchymal damage to the kidneys. Postrenal or obstructive AKI is characterized by acute obstruction of the urinary tract, including ureters or bladder outlet (Box 55.2). In intrinsic AKI, acute injury to the renal parenchyma underlies the development of kidney dysfunction, as is seen in acute tubular necrosis (ATN), acute interstitial nephritis (AIN), and acute glomerulonephritis (AGN) (Box 55.3). Categorizing the forms of AKI in this fashion is useful for didactic purposes and is helpful in guiding the initial assessment of the patient with AKI, but substantial overlap may exist among these categories, particularly between prerenal and intrinsic causes of AKI. For example, renal hypoperfusion may cause a spectrum of renal dysfunction ranging from mild prerenal azotemia to overt ATN, depending upon its severity and duration. Even in patients with classic clinical presentations of volume depletion–associated prerenal AKI sensitive clinical markers of tubular injury may be elevated.⁴⁰ Thus, precise categorization of the cause of AKI into one of these categories may not be possible, and overlap and transition among categories may occur.

Box 55.1 Mechanisms and Causes of Prerenal Acute Kidney Injury

PRERENAL ACUTE KIDNEY INJURY

Prerenal azotemia caused by extracellular fluid volume loss or volume sequestration, reduced cardiac output, systemic vasodilation, intrarenal vasoconstriction, or increased renal venous pressure is the most common cause of AKI (see Box 55.1), contributing to the development 30% to 60% of all cases.^{17-19,24} The primary pathogenesis of prerenal azotemia is a decrease in effective glomerular perfusion. This form of AKI, if treated early, is usually readily reversible; however, if left untreated, renal ischemia with resultant ATN may result.

In classic forms of prerenal azotemia, reduced renal perfusion pressure and afferent arteriolar constriction combine to lower glomerular capillary hydrostatic pressure and the formation of glomerular ultrafiltrate.^{1,41,42} Prerenal azotemia develops when the capacity of the usual physiologic responses to hypovolemia is exceeded and GFR falls. In response to hypovolemia there is a decrease in mean arterial pressure, triggering baroreceptors that ultimately lead to activation of the sympathetic nervous system, activation of the renin-angiotensin-aldosterone system (RAAS), and secretion of the antidiuretic hormone vasopressin.

Activation of the renal sympathetic nerves constricts the afferent (preglomerular) arterioles and stimulates release of renin from the juxtaglomerular apparatus. Renin secretion is also directly stimulated in response to hypovolemia by changes in intrarenal hemodynamics. Secretion of renin activates a cascade in which angiotensinogen is cleaved to form angiotensin I, which is then cleaved by angiotensin-converting enzyme released by local endothelium to form angiotensin II. Angiotensin II stimulates both afferent and efferent (postglomerular) arteriolar vasoconstriction; however, the effect on the afferent vessel is opposed by vasodilatory prostaglandins, kallikrein, kinins, and nitric oxide.^{43,44} The net effect is to maintain the tone of the afferent arteriole while constricting the efferent vessel, returning intraglomerular pressure and glomerular ultrafiltration toward normal. In addition, angiotensin II stimulates proximal tubular sodium reabsorption and, through its action as an aldosterone secretagogue, increases plasma aldosterone levels and stimulates distal tubular sodium reabsorption. Increased vasopressin levels stimulate water and urea reabsorption in the collecting duct. The net effect of modest hypovolemia is maintenance of the GFR at near normal levels accompanied by production of concentrated urine with low sodium content and a decrease in the fractional excretion of urea. When effective volume depletion exceeds the normal physiologic compensatory mechanisms, the GFR falls and overt prerenal AKI ensues.

Multiple medications can exacerbate the development of prerenal AKI. The prerenal form of AKI complicating

diuretic use is caused by extracellular volume depletion. With nonsteroidal anti-inflammatory drugs (NSAIDs), including both nonselective and cyclooxygenase 2 (COX-2)-selective agents, the inhibition of cyclooxygenase leads to depletion of renal vasodilatory prostaglandins that normally counteract the afferent arteriolar constricting effect of angiotensin II and increased renal adrenergic tone.⁴⁵⁻⁴⁷

In situations in which vasoconstrictor mechanisms are activated, such as volume depletion, heart failure, sepsis, cirrhosis, and nephrotic syndrome, and in patients with chronic kidney disease, the use of NSAIDs may result in severe afferent vasoconstriction, severely reducing glomerular capillary filtration pressure and causing AKI. If promptly discontinued, NSAID-induced AKI can be reversible; however, if NSAIDs continue to be administered ATN may ensue.

Angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), and direct renin inhibitors act by inhibiting the RAAS. Inhibition of angiotensin II production by direct renin inhibitors and ACEIs or blockade of its action by ARBs prevents angiotensin

II-mediated constriction of the efferent arteriole and diminishes glomerular capillary filtration pressure. Although this effect is desirable in preventing hyperfiltration injury in patients with CKD, the use of these agents may contribute to the development of AKI in the setting of renal hypoperfusion, when maintenance of glomerular filtration is dependent upon activation of renin and angiotensin II.⁴⁸ This is particularly likely to happen when therapy is initiated or escalated and volume depletion or hypotension supervenes in patients with renal artery stenosis, CKD, heart failure, or liver disease. The prerenal azotemia that may develop in these settings is usually reversible if the offending agent is promptly discontinued; however, these agents have also been associated with an increased risk of ATN.⁴⁹

Although the majority of forms of prerenal AKI are mediated by decreased renal perfusion, altered intrarenal hemodynamics may result in decreased GFR despite increased organ perfusion. Early in sepsis, renal perfusion may be increased; however, GFR may fall as the result of decreased efferent arteriolar tone, resulting in decreased glomerular capillary filtration pressure.⁵⁰

Increases in renal venous pressure may also contribute to the development of prerenal AKI. As renal venous pressure increases, renal perfusion pressure falls; in addition, renal parenchymal pressure increases as venous pressure rises, narrowing the pressure gradient driving glomerular filtration.^{51,52} Two settings in which renal venous congestion results in a prerenal state are the abdominal compartment syndrome and heart failure. Abdominal compartment syndrome (ACS) typically develops in critically ill patients, most commonly in the setting of trauma with abdominal hemorrhage, abdominal surgery, massive fluid resuscitation, liver transplantation, and gastrointestinal conditions including peritonitis and pancreatitis. ACS is defined by an intra-abdominal pressure of 20 mm Hg or higher associated with dysfunction of one or more organ systems.⁵³ However, intra-abdominal pressures lower than 20 mm Hg may be associated with ACS, while values higher than this threshold do not universally lead to the ACS.⁵⁴⁻⁵⁷ Oliguria, which can lead to anuria, often develops and, as is true for other forms of AKI associated with impaired renal perfusion, urine sodium concentration is commonly reduced. Renal venous congestion associated with modest increases in intra-abdominal pressure has also been shown to contribute to the acute renal dysfunction accompanying acute decompensated heart failure.^{58,59}

POSTRENAL ACUTE KIDNEY INJURY

AKI resulting from obstruction usually accounts for fewer than 5% of ICU-associated AKI.¹⁹ Urinary tract obstruction may occur at any level of the renal collecting system, beginning at the renal pelvis and ending at the urethra (see [Box 55.2](#)). Obstruction above the level of the bladder is referred to as upper tract obstruction and may result from either intrinsic (intraluminal) or extrinsic disease. The development of AKI from upper tract obstruction requires the presence of bilateral obstruction or unilateral obstruction in the setting of a single functioning kidney or dysfunction of the contralateral kidney. Common causes for upper tract obstruction include luminal obstruction from ureteric calculi, blood clots, urothelial tumors, sloughed renal papillae or ureteral strictures, and external compression from retroperitoneal and pelvic tumors, adenopathy, hematomas, or retroperitoneal fibrosis. More commonly, obstruction occurs at the level of the bladder neck or urethra, as may occur with benign prostatic hypertrophy or prostate cancer, bladder tumors, and bladder stones. Neurogenic bladder dysfunction associated with diabetes mellitus, autonomic neuropathy, and spinal cord disease may also contribute to the development of obstructive disease. Treatment with narcotics and agents with anticholinergic action may exacerbate subclinical voiding dysfunction and precipitate acute urinary retention in the setting of acute illness.

Patients with obstructive disease may present with anuria if obstruction is complete, with normal or even increased urine volume in the setting of partial obstruction, or with fluctuating urine output with periods of anuria alternating with rapid passage of urine as the pressure in the collecting system rises and overcomes the obstructing disease. In the acute phase of obstruction, intratubular pressure rises, resulting in a reduction in glomerular filtration pressure. As the obstruction persists, renal blood flow diminishes,

intratubular pressures fall toward normal, but GFR remains severely depressed. Relief of the obstruction with placement of a bladder catheter for lower tract obstruction or ureteral stents or percutaneous nephrostomy tubes for upper tract obstruction usually results in prompt return of GFR if the duration of obstruction has not been excessive.⁶⁰

INTRINSIC ACUTE KIDNEY INJURY

The causes of intrinsic AKI can be categorized based on the anatomic compartments of the kidney that are involved (see [Box 55.3](#)). Using this approach, intrinsic AKI is commonly divided into tubular, interstitial, glomerular, and vascular processes. In addition, in a variety of settings the primary pathophysiology consists of intratubular deposition of crystals or protein. These latter syndromes could be considered as a subset of acute tubular disease, but given the striking difference in pathogenesis, these disorders will be discussed separately in this chapter. It is also important to recognize that although this approach provides a construct for understanding the multitude of causes of intrinsic AKI, there are substantial overlaps among categories. Thus, small vessel vasculitides with predominant glomerular involvement could be classified either with acute glomerulonephritis or as a renal vascular disorder. Similarly, interstitial inflammation may play a substantial role in the pathogenesis of ATN, blurring the distinction with acute interstitial nephritis (AIN).

ACUTE TUBULAR NECROSIS

The most common intrinsic cause of AKI is ATN, accounting for 85% to 90% of intrinsic ICU-associated AKI.^{19,24} The causes of ATN can be broken down into three major categories: ischemia-reperfusion injury, nephrotoxins, and sepsis (see [Box 55.3](#)). There is, however, significant overlap between septic and ischemic ATN; many, although not all, cases of sepsis-associated ATN develop in the setting of septic shock, and sepsis-associated ATN has frequently been classified as a subcategory of ischemic ATN.⁶¹ Data suggest, however, that sepsis-associated ATN has unique features and may develop in the absence of overt renal ischemia and should be considered as a separate etiologic category.⁶²⁻⁶⁴ Nephrotoxic ATN can result from toxicity from the endogenous heme pigments myoglobin and hemoglobin or may be caused by exogenous toxins, most commonly medications such as aminoglycosides, amphotericin B, and cisplatin. In many patients, multiple etiologic factors are present and the ATN must be characterized as multifactorial.

A description of the pathophysiologic mechanisms thought to underlie ischemic, septic, and nephrotoxic causes of ATN are provided in the online supplement at www.expertconsult.com.

ACUTE INTERSTITIAL NEPHRITIS

AIN constitutes approximately 5% to 10% of intrinsic AKI in the ICU setting and is defined by the presence of lymphocytic infiltration of the kidney (see [Box 55.3](#)). AIN is most commonly related to medication use but may also be associated with a wide variety of infections, autoimmune disorders, and malignancy.⁸⁸ The most common offending medications include penicillin, cephalosporin, sulfonamide, and quinolone antibiotics; proton pump

Although the characteristic histologic lesion in ATN is epithelial cell injury with tubular cell necrosis or apoptosis, the pathophysiology of ATN also includes endothelial cell damage and activation of inflammatory pathways. Although all segments of the nephron may be affected, proximal tubular epithelial cells at the corticomedullary junction and outer stripe of the medulla are most susceptible to ischemic injury.⁶⁵ More proximal tubular segments are involved in toxic nephropathy as a result of their transport and endocytotic pathways that lead to increased cellular uptake of the toxin.

Ischemic injury results in depletion of cellular adenosine triphosphate (ATP) in the tubular epithelial cells leading to disruption of the cytoskeleton.⁶⁶ Maintenance of the cytoskeleton is critical to the functional integrity of the tubular epithelium; its loss leads to disruption of the luminal (apical) brush border membrane and of the adhesion proteins that are critical for maintaining attachment to the basement membrane and for the integrity of the tight junctions between adjacent cells. With their loss, transport proteins such as Na^+/K^+ -ATPase that are normally restricted to the apical or basolateral domains can migrate and normal vectorial transport of sodium and other solutes from tubular lumen to blood is disrupted.⁶⁷ This may account, in part, for the elevated urine sodium and fractional excretion of sodium often seen in patients with ATN. The loss of attachment to the basement membrane leads to the sloughing of cells into the tubular lumen. Severe ATP depletion may lead to cell necrosis, but less severe injury activates apoptotic pathways, which appear to be the predominant mechanism of cell death in ATN.⁶⁸ In addition, ATP depletion leads to a rise in intracellular calcium, which serves as a further mediator of cell damage.

In addition to epithelial injury, endothelial damage and microvascular dysfunction play a central role in the pathogenesis of ischemic and septic ATN. Endothelial damage results in increased expression of adhesion molecules, leukocyte and platelet adhesion, activation of coagulation pathways, vascular congestion, and obstruction resulting in diminished blood flow through the renal microvasculature.⁶⁹ The endothelial and epithelial cell injury also leads to recruitment of leukocytes and activation of inflammatory pathways.^{70,71} The combination of endothelial damage and inflammation may amplify the tubular injury, even after the inciting insult has resolved.⁶⁹

The reduction in GFR in ATN is the result of several factors.¹ Early in ischemic ATN, the combined influence of a decrease in renal perfusion pressure and afferent arteriolar constriction initiates the reduction in glomerular filtration. Later, endothelial damage and microvascular obstruction contribute to the persistence of decreased glomerular filtration. Sloughed debris from necrotic and apoptotic tubular epithelial cells and nonadherent viable cells form obstructing intratubular casts, increasing intratubular hydrostatic pressure and further decreasing glomerular filtration. When these casts pass into the urine they are the “muddy brown” granular casts that are characteristic of ATN. Finally, “back-leak” of filtrate across the denuded tubular basement membrane contributes to the loss of effective GFR.

The clinical course of AKI can be conceptualized as consisting of four phases.⁷² The initial inciting injury is

followed by an extension phase during which the endothelial and inflammatory processes result in extension of the tubular injury despite resolution of the triggering insult. The extension phase is followed by a maintenance phase of variable duration during which the GFR remains very low. During this phase, tubular epithelial cells are believed to undergo a process of dedifferentiation and proliferation, repopulating the tubular basement membrane. Finally there is a recovery phase, in which the tubular epithelial cells redifferentiate and reestablish a normal tubular epithelium and GFR recovers. To the extent that repair to the tubular epithelium is complete, kidney function can recover to near normal levels; however, to the extent that fibrotic pathways are activated and there is rarefaction of the capillary bed, recovery of kidney function will be incomplete.⁷³⁻⁷⁵

ATN also exhibits distant organ effects. In experimental models, renal ischemia reperfusion injury is associated with alterations in cardiac, pulmonary, hepatic, and brain function.⁷⁶⁻⁷⁸ It is postulated that these distant organ effects are mediated by systemic inflammatory changes, activation of proapoptotic pathways, increases in leukocyte trafficking, and dysregulated channel expression and that these distant effects may contribute to nonrenal organ dysfunction in patients with ATN.

The precise mechanisms by which sepsis causes ATN have not been elucidated. In septic shock, renal hypoperfusion likely predominates.⁶¹ In less severe sepsis the pathophysiology is thought to include a combination of intrarenal hemodynamic changes; endothelial dysfunction; infiltration of the renal interstitium by lymphocytes, neutrophils, and mononuclear cells; and activation of both pro- and anti-inflammatory mechanisms.⁶² The precise role of individual mediators in the pro- and anti-inflammatory pathways, including tumor necrosis factor- α interleukin (IL) 1, IL-6, and IL-10, is uncertain.

The pathophysiologic process by which nephrotoxins induce renal damage is incompletely understood and most likely differs from agent to agent.^{46,79} Several of the more commonly encountered nephrotoxins in the ICU setting are aminoglycoside antibiotics, amphotericin B, and iodinated radiocontrast agents. Aminoglycosides generally induce mild (mean rise in serum creatinine of 1 to 3 mg/dL), nonoliguric ATN in 5% to 20% of patients receiving a 7- to 10-day course of therapy.^{80,81} However, even brief exposure in the setting of impaired renal perfusion can induce some renal damage. Aminoglycosides are avidly taken up by the proximal tubular epithelial brush border via a megalin-dependent mechanism. Once within the cell they are transported to the endoplasmic reticulum and then enter the cytosol. Once in the cytosol, the aminoglycoside disperses to various intracellular organelles, such as mitochondria, where it mediates organelle-specific toxicity.⁸² Risk factors for aminoglycoside nephrotoxicity include the use of high doses or prolonged courses of therapy, volume depletion, diabetes mellitus, advanced age, baseline CKD and the presence of hypovolemia, renal ischemia, or concomitant administration of other nephrotoxins.^{81,83}

Radiocontrast agents are relatively nontoxic in healthy individuals with an incidence of contrast nephropathy of less than 1%.^{84,85} Risk factors for the development of contrast-induced AKI include preexistent kidney disease, diabetes

mellitus, effective intravascular volume depletion, concomitant therapy with NSAIDs, and exposure to high doses and repeated doses of the contrast agent. The precise mechanism of toxicity is not understood. Administration of radiocontrast agents induces marked renal vasoconstriction, mediated in part by endothelin. The osmotic load and altered flow through the microvasculature due to the high viscosity of the contrast media induces medullary hypoxia. The hypoxia as well as direct effects of the contrast agents induces the generation of reactive oxygen species that may cause membrane and DNA damage. In addition, direct cytotoxicity to renal epithelial cells can be demonstrated. The risk of contrast nephropathy can be mitigated by the use of relatively less toxic low- and isosmolar agents, as compared to the older and more nephrotoxic high-osmolar agents and by administration of intravenous fluids to correct volume depletion and maintain high urine flow rates.

Myoglobin and hemoglobin are endogenous heme-containing proteins that are associated with the develop-

ment of ATN.^{86,87} Myoglobinuric AKI is much more common than hemoglobinuric disease. Myoglobin is released during muscle injury and is freely filtered by the glomerulus. In contrast, hemoglobin released during intravascular hemolysis is normally bound by haptoglobin; hemoglobinuria will only develop when hemolysis is severe enough to overwhelm the binding capacity of haptoglobin, such as may occur with an ABO-incompatible blood transfusion. Renal injury in pigment nephropathy is due to a combination of factors including volume depletion, particularly in rhabdomyolysis, in which there is sequestration of fluid in the injured muscle, renal vasoconstriction, direct heme-pigment mediated cytotoxicity, and intraluminal cast formation. Despite the toxicity of the heme pigments, AKI is uncommon in the absence of volume depletion, acidosis, and possibly mild ischemia. Prevention of nephropathy in patients with rhabdomyolysis or hemolysis focuses on maintaining adequate extracellular fluid volume and renal perfusion.

inhibitors; phenytoin; allopurinol; and NSAIDs. The classic presentation of medication-associated AIN includes fever, rash, and eosinophilia; however, this complete triad is present in fewer than one third of patients and is unusual in NSAID-associated AIN. Characteristic urinary findings include hematuria and pyuria and white blood cell casts in the absence of infection. Eosinophiluria may also be present but is neither a sensitive nor a specific finding. Although the diagnosis may be made based on clinical setting, history of medication use, and urinary findings, definitive diagnosis usually requires kidney biopsy.

ACUTE GLOMERULONEPHRITIS

Acute glomerular disease is an uncommon cause of AKI in the ICU. These forms can include postinfectious glomerulonephritis, rapidly progressive glomerulonephritis, systemic lupus erythematosus, and a broad range of systemic vasculitides with renal involvement. The characteristic finding in acute glomerular disease is the presence of dysmorphic red blood cells and red blood cell casts on urinalysis. Although serologic tests may help guide the diagnosis, definitive diagnosis usually requires kidney biopsy. Prompt diagnosis of acute glomerular disease is critical for guiding therapy with time to initiation of treatment being a critical factor in the response to therapy.

Several causes of acute glomerular disease deserve special mention because they often present as pulmonary-renal syndromes with acute glomerular disease and pulmonary hemorrhage. These causes include anti-glomerular basement membrane (anti-GBM) disease, antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (granulomatosis with polyangiitis or microscopic polyarteritis), and systemic lupus erythematosus.

ACUTE VASCULAR SYNDROMES

Acute vascular syndromes are divided into large vessel (renal artery and renal vein) and small vessel disease. Large vessel diseases include thrombosis, thromboembolism and dissection of the renal arteries, and renal vein thrombosis.^{89,90} Acute arterial or venous occlusion may present with renal infarction. With unilateral or subtotal disease, the presentation usually consists of pain and hematuria. Lactate dehydrogenase levels will be elevated and the diagnosis made by contrast-enhanced computed tomography (CT) or nuclear scintigraphy. As with obstructive disease, AKI is the presenting manifestation only when there is bilateral involvement or unilateral disease with an absent or nonfunctional contralateral kidney.

Multiple conditions can affect the renal microvasculature and present with AKI, including the systemic vasculitides (discussed earlier) that present with primarily glomerular involvement. Other diseases with predominant renal microvascular involvement leading to AKI include malignant hypertension, scleroderma renal crisis, toxemia of pregnancy, and the microangiopathic hemolytic diseases, hemolytic-uremic syndrome, and thrombotic thrombocytopenic purpura. Atheroembolic disease represents another important disease of the renal microvasculature that may present as acute or subacute kidney disease.^{91,92} Atheroembolic disease is characterized by the systemic showering of atheromatous debris to the distal branches of the arterial

tree. Although atheroembolism may occur spontaneously, it develops most commonly after cardiac or aortic angiography or surgery, or in association with systemic anticoagulation or thrombolytic therapy. Involvement is generally systemic with common manifestations including cutaneous livedo reticularis and digital ischemia and gastrointestinal, hepatic, and nervous system involvement. Because the kidneys receive approximately 20% of the cardiac output, renal involvement is common, ranging from renal infarction to AKI to a subacute and stuttering decline in kidney function.

INTRATUBULAR OBSTRUCTION

AKI may also occur as the result of crystalline or proteinaceous obstruction of the renal tubules. In acute tumor lysis syndrome, AKI often results from intratubular deposition of uric acid.^{93,94} Following ethylene glycol ingestion and in certain inborn errors of metabolism, the major mechanism for development of AKI is intratubular deposition of calcium oxalate. A number of medications have also been associated with acute crystalline nephropathy, including acyclovir, methotrexate, indinavir, triamterene, and sulfadiazine.^{95,96} In multiple myeloma, tubular obstruction by monoclonal light chains (Bence-Jones protein) is the cause of acute myeloma kidney disease.^{97,98}

CLINICAL MANIFESTATIONS

The manifestations of AKI may range from asymptomatic laboratory abnormalities associated with early or mild disease to a constellation of symptoms including oliguria, volume overload, and overt uremic manifestations accompanied by acidosis and electrolyte derangements. A fundamental difficulty in the diagnosis of AKI is the absence of reliable bedside methods to reliably measure GFR and rapidly detect changes in kidney function. Most commonly AKI is recognized based on increases in the concentration of urea or creatinine in the blood or as the result of sustained decreases in urine output.

RETENTION OF FILTRATION MARKERS

Urea and creatinine are primarily excreted by glomerular filtration. A sudden decrease in GFR will result in rising concentrations of these solutes in the blood. However, the relationship between the GFR and their concentration is nonlinear and may be affected by a variety of other factors.

UREA

Urea is the major end product of nitrogen metabolism. Blood urea concentration, commonly assayed as blood urea nitrogen (BUN), is dependent upon the balance between hepatic synthesis and renal excretion. Increased urea generation resulting in elevations in the BUN in the absence of a marked decrease in GFR may result from high dietary protein intake, amino acid loading during parenteral nutrition, and the endogenous protein load from gastrointestinal hemorrhage as well as in hypercatabolic states associated with fever, sepsis, and glucocorticoid administration or

inhibition of protein synthesis as may be seen with tetracycline antibiotics. Hypercatabolic states may also result in increases in BUN during AKI that exceed the increase of 10 to 20 mg/dL/day that usually is typically associated with absence of glomerular filtration.⁹⁹ Normally, filtered urea is partially reabsorbed along the length of the nephron, with increased reabsorption in states of low urine flow. In volume depletion, severe heart failure, and obstructive uropathy, increased tubular reabsorption of urea often results in increases in the BUN that are disproportionate to the fall in GFR. This variability in the synthesis of urea and the non-GFR-related factors that influence its urinary excretion render the BUN a less reliable marker of GFR than the serum creatinine concentration. However, the level of BUN generally correlates with symptoms of renal failure, with uremic manifestations usually absent until the BUN is greater than 100 mg/dL.

CREATININE

Creatinine is derived from the nonenzymatic hydrolysis of creatine, which is usually released at a constant rate from skeletal muscle and is excreted primarily by filtration at the glomerulus. In patients with normal kidney function, less than 10% of creatinine excretion occurs by tubular secretion, although this percentage increases in CKD. There is essentially no tubular reabsorption of creatinine. This relationship allows creatinine to serve as a reliable endogenous marker of glomerular filtration when the creatinine concentration is in steady state. Because much of the interindividual variability in creatinine production can be accounted for based on demographic and clinical variables including age, gender, race, and weight, it is possible to reliably estimate creatinine clearance or GFR from the serum creatinine concentration.^{8-10,12} The confidence intervals around these estimates are wide, however, and these estimates should not be interpreted as precise measures of kidney function. In the absence of glomerular filtration, serum creatinine typically increases by 1 to 2 mg/dL/day.¹⁰⁰ This increase is influenced by numerous factors including the magnitude of decrement in GFR, the rate of creatinine production, and changes in the volume of distribution.¹⁰⁰ For example, creatinine production may be reduced in sepsis,¹⁰¹ and increased in the setting of skeletal muscle injury (rhabdomyolysis). Aggressive volume resuscitation may also mask any increase in serum creatinine through dilution.¹⁰² Thus, although a sudden increase in serum creatinine concentration is the most common parameter triggering recognition of AKI, the use of estimating equations for GFR are not reliable in critically ill patients with AKI. There are several other factors that may also impair the reliability of serum creatinine as a marker of kidney function in critical illness. Some medications, most notably trimethoprim and cimetidine, block tubular secretion of creatinine, leading to an increase in serum creatinine concentration in the absence of decreased kidney function.¹⁰³ This effect is generally minimal in patients with normal kidney function, but the increase in serum creatinine may exceed 30% in patients with underlying CKD. Reported creatinine concentrations may also be increased as a result of chemical interference with some assay methods by ketone bodies or by medications, such as cefoxitin.¹⁰³ One final drawback to the use of

creatinine as a marker of kidney function in patients with AKI is the inverse relationship between serum creatinine concentrations and GFR. Thus, significant reductions in GFR may occur prior to the serum creatinine concentration being recognized as increasing.

CYSTATIN C

Given the drawbacks to urea and creatinine as markers of kidney function, other readily available markers of GFR have been sought. The use of exogenous filtration markers such as inulin, iothalamate, or iothexol is cumbersome and not practical for the recognition of abrupt changes in kidney function. Cystatin C has been proposed as a more sensitive endogenous marker of GFR, including in ICU patients.¹⁰⁴⁻¹⁰⁶ Cystatin C is a cysteine protease inhibitor that is released into the bloodstream at a constant rate from all nucleated cells. It is readily filtered at the glomerulus and reabsorbed and catabolized by renal proximal tubular epithelial cells such that virtually no cystatin C appears in the urine. The interindividual variability in cystatin C production appears to be less than that for creatinine. Thus, in steady-state situations cystatin C may be a more reliable marker of GFR.¹⁰⁷ In addition, the serum half-life of cystatin C is shorter than that of creatinine, making it a more sensitive marker for acute changes in GFR.¹⁰⁴⁻¹⁰⁶ However, cystatin C assays are not currently readily available in the acute setting, and the optimal place for cystatin C in the detection of AKI in at-risk critically ill patients remains to be determined.

MARKERS OF TUBULAR INJURY

A number of markers of tubular injury have been proposed as novel diagnostic tests for the early diagnosis of AKI. These markers include kidney injury molecule-1 (KIM-1),^{108,109} neutrophil gelatinase-associated lipocalin (NGAL),¹¹⁰⁻¹¹⁶ interleukin 18 (IL-18),¹¹⁴⁻¹¹⁸ liver fatty acid binding protein (L-FABP)^{40,119} and α - and π -glutathione-S-transferase (GST),^{120,121} among others. Even though these markers have shown promise, their role in the clinical care of patients at risk for AKI remains uncertain.

OLIGOANURIA

Decreased urine output represents a second major reason for recognition of AKI. Sustained oliguria, which is usually defined as a urine output of less than 400 to 500 mL/day, or a sustained urine output of less than 20 mL/hour, in the absence of overt volume depletion almost always indicates the presence of AKI.⁷ Although oliguria is often considered to be a cardinal feature of AKI, most cases of AKI in the critically ill are nonoliguric.¹²² Thus, although sustained oliguria should suggest prompt the evaluation for AKI, the presence of a well-maintained urine output should not be construed to represent the presence of adequate kidney function. Anuria (the absence of urine output) always demands prompt attention. True anuria is most often caused by complete urinary obstruction but may also be seen with vascular catastrophes with bilateral renal infarction and less commonly with severe rapidly progressive glomerulonephritis. Rarely, severe ATN may result in a short period of complete anuria.

DETECTION OF BIOCHEMICAL OR CLINICAL COMPLICATIONS

An additional way in which AKI may come to the attention of the clinician is by the detection of one of the biochemical or clinical consequences of the loss of kidney function. Thus, occasionally, the development of fluid overload, mental status changes, hyperkalemia, metabolic acidosis, hypocalcemia, hyperphosphatemia, hyperuricemia, or anemia may be the initially recognized manifestation of AKI.

DIAGNOSTIC APPROACH

GENERAL ASPECTS

The first step in evaluating the patient with AKI is to determine whether it is primarily prerenal or postrenal in origin or is due to intrinsic renal disease. Although this division is useful for conceptualizing and categorizing the causes of AKI, it is important to recognize that many patients may not fall neatly into a single category. For example, prerenal azotemia and ischemic ATN fall on a continuum; a process that may start out as pure prerenal azotemia may evolve over time into ischemic ATN. This blurring between these broad categories is further evidenced by the fact that markers of tubular epithelial cell injury are elevated in patients with classic presentations of prerenal azotemia.⁴⁰ Moreover, most cases of AKI encountered in ICU patients have more than a single cause,* with the single most common condition predisposing to AKI in the critically ill patient being sepsis and with the majority of patients having AKI in the setting of multiple organ failure.^{24,61,125} The evaluation of the patient should begin with a careful review of the history and physical examination with particular attention to hemodynamic status, episodes of hypotension and infection, and the record of medication administration. Assessment of voiding function and postvoiding residual bladder volume should be performed to exclude bladder outlet obstruction. This step should then be followed by microscopic examination of the urine and evaluation of urine electrolytes. Renal imaging may be necessary to evaluate for upper tract obstruction or to evaluate for patency of the renal vasculature. In a minority of patients, a renal biopsy will be required for definitive diagnosis.

HISTORY, PHYSICAL EXAMINATION, AND RECORD REVIEW

The initial step in attempting to identify the cause of AKI should be a thorough history, physical examination, and review of the medical record. The overall clinical setting, recent events in the patient's illness, use of medications, and possible toxic exposures should be noted, with particular attention to events during the 1- to 2-day interval prior to the onset of AKI. A history of vomiting, blood loss, diarrhea, diuretic use, burns, or symptoms compatible with decompensation of heart failure or of liver disease suggests

potential prerenal azotemia. A history of prostatism with intermittency, hesitancy, or decrease in the force of the urinary stream; history of urologic, gynecologic, or other pelvic or retroperitoneal malignancy; flank or suprapubic pain; or hematuria or pyuria may suggest obstructive (postrenal) disease. The history of a systemic disorder, fever, rash, vascular disease, or musculoskeletal complaints is compatible with a renovascular, glomerular, or interstitial disorder. Review of the medical record should focus on indices of volume status including intake and output records, serial weights, and serial measurements of blood pressure to help assess for risk factors for intravascular volume depletion and prerenal azotemia. Delineation of the pattern of urine output is often helpful. Finally, a careful review of medication records to assess for exposure to potential nephrotoxins is critical.^{46,79}

The physical examination should focus on assessing for evidence of intravascular volume depletion, such as orthostatic changes in pulse and blood pressure, dry mucous membranes, decreased skin turgor, longitudinal tongue furrows, and absence of sweat in the axilla and inguinal regions.¹²⁶ A fall in systolic blood pressure of more than 20 mm Hg and in diastolic blood pressure of more than 10 mm Hg accompanied by an increase in heart rate of more than 30 beats per minute is suggestive of intravascular volume depletion. However, these findings are neither sensitive nor specific. Orthostatic changes in blood pressure may be absent in some patients despite significant intravascular volume depletion and may be observed in the absence of volume depletion in patients with autonomic dysfunction and in the elderly. Examination for neck vein distention, pulmonary rales, ventricular gallops, and pedal edema may indicate the presence of heart failure. Occasionally, a chest radiograph, cardiac function testing (i.e., an echocardiogram or nuclear gated blood pool scan), or assessment of plasma brain natriuretic peptide (BNP) or N-terminal pro-BNP (NT-proBNP) levels may assist in the diagnosis of heart failure. Accurate assessment of extracellular fluid volume status and cardiac function may be difficult on clinical grounds, particularly in immobilized, mechanically ventilated ICU patients, and invasive monitoring of central venous pressure, or less commonly, pulmonary artery and pulmonary capillary occlusion pressure, and assessment of cardiac output may be helpful. Assessment for ascites and abdominal distention may assist in the diagnosis of AKI associated with liver disease or the abdominal compartment syndrome. Abdominal palpation to detect flank, suprapubic or central abdominal masses may be helpful in assessing the presence of obstructive uropathy or for an abdominal aortic aneurysm with possible renovascular compromise. A bladder scan or placement of a bladder catheter to assess postvoid bladder volume in patients who do not have an indwelling bladder catheter should be performed to help exclude bladder outlet obstruction as a cause of obstructive uropathy. A rectal and pelvic examination may also be helpful in assessing for possible causes of obstructive uropathy. Careful examination of the skin may detect rashes compatible with a drug-induced eruption, which may suggest drug-induced acute interstitial nephritis; palpable purpura, suggesting a microangiopathic hemolytic anemia such as hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura or a systemic vasculitis, such as

*See references 18, 19, 21, 22, 24, 123, and 124.

cryoglobulinemia; and *livedo reticularis* or digital ischemia, suggesting atheroembolic disease.

URINALYSIS AND URINE INDICES

Assessment of urine composition and examination of the urine sediment can assist in determining the cause of AKI (Table 55.4). The electrolyte composition of the urine may be helpful in differentiating between prerenal azotemia and ATN.¹²⁷⁻¹³⁰ In prerenal azotemia, renal tubular function is intact and the tubules avidly reabsorb sodium in an effort to restore extracellular fluid volume and renal perfusion to normal. Thus, in prerenal azotemia, urine sodium concentrations are usually less than 20 mmol/L and the fractional excretion of sodium [calculated as $(U_{Na}/P_{Na}) \div (U_{Cr}/P_{Cr})$, where U_{Na} is the urine sodium concentration, P_{Na} is the plasma or serum sodium concentration, U_{Cr} is the urine creatinine concentration, and P_{Cr} is the plasma or serum creatinine concentration] is less than 1%. In contrast, in ATN, the damaged renal tubular cells fail to reabsorb sodium normally, perhaps because of loss of cellular polarity, with a resultant urine sodium concentration greater than 40 mmol/L and a fractional excretion of sodium above 2%. It needs to be recognized, however, that these urinary electrolyte findings are not absolute. Thus, increased fractional excretion of sodium may occur in prerenal states when diuretics have been administered, in patients with underlying CKD who may take several days after the onset of volume depletion to maximize sodium conservation, in the presence of glycosuria or other osmotic diuresis, or in the presence of bicarbonaturia. A fractional excretion of sodium of less than 1% may be present in multiple settings other than prerenal azotemia, including in the absence of any kidney disease and in many forms of glomerulonephritis, in

microangiopathic hemolytic anemia, and in some forms of ATN, including radiocontrast-associated AKI, myoglobinuric ATN, early sepsis-associated ATN, and nonoliguric ATN.^{131,132} The fractional excretion of urea [calculated as $(U_{urea}/P_{urea}) \div (U_{Cr}/P_{Cr})$, where U_{urea} is the urine urea nitrogen concentration, P_{urea} is the blood urea nitrogen concentration, U_{Cr} is the urine creatinine concentration, and P_{Cr} is the plasma or serum creatinine concentration] has been proposed as an alternative index of tubular function for the diagnosis of prerenal azotemia in patients who have received diuretic therapy.¹³³⁻¹³⁶ The normal fractional excretion of urea is greater than 60%; in reversible prerenal states, values typically fall to less than 35%. Urinary chemical indices are not of value in establishing the diagnosis of obstructive uropathy.

Urine microscopy is also often very helpful in determining the cause of AKI.¹³⁷⁻¹⁴¹ A normal urine sediment suggests the presence of either a prerenal or postrenal cause of AKI, although obstructive uropathy may be associated with hematuria, pyuria, or crystalluria. In the presence of proteinuria a urinary sediment containing abundant cells or casts suggests an intrinsic cause of AKI. Specifically, the presence of many renal tubular epithelial cells, epithelial cell casts, or pigmented (muddy brown) granular casts suggests the diagnosis of ATN and has been associated with increased risk for greater severity of disease.^{141,142} The presence of white blood cells and white blood cell casts suggests AIN. Although eosinophiluria may be seen in association with interstitial nephritis, it is also associated with atheroembolic disease and with urinary tract infections, and the specificity and sensitivity of this finding are limited.¹⁴³ The presence of dysmorphic red blood cells (which are best seen using phase contrast microscopy) and red blood cell casts suggests the presence of an acute glomerulonephritis or vasculitis

Table 55.4 Urinalysis Findings in Acute Kidney Injury (AKI)

Etiologic Disorder	Urine Chemistry	Urine Sediment
Prerenal	$U_{Na} < 20$ mmol/L $FE_{Na} < 1\%$ $FE_{urea} < 35\%$	Normal or nearly normal (hyaline casts and rare granular casts)
Acute tubular necrosis	$U_{Na} > 40$ mmol/L $FE_{Na} > 2\%$ $FE_{urea} > 60\%$	Renal tubular epithelial cells, epithelial cell casts, coarse pigmented (muddy brown) casts
Acute interstitial nephritis	Variable; U_{Na} may be > 40 mmol/L, FE_{Na} may be $> 2\%$	Red blood cells, white blood cells, white blood cell casts, eosinophils
Acute glomerulonephritis	Variable; U_{Na} may be < 20 mmol/L, FE_{Na} may be $< 1\%$	Red blood cells (dysmorphic), red blood cell casts
Acute vascular disease	Variable; U_{Na} may be < 20 mmol/L, FE_{Na} may be $< 1\%$	Red blood cells, red blood cell casts in HUS/TTP, eosinophils in atheroembolic disease
Crystal-associated AKI	Variable	Crystalluria Uric acid crystals in tumor lysis syndrome Calcium oxalate crystals in ethylene glycol ingestion Drug crystals (acyclovir, methotrexate, indinavir, triamterene, sulfadiazine)
Obstructive	Variable; early U_{Na} may be < 20 mmol/L, FE_{Na} may be $< 1\%$; late U_{Na} may be > 40 mmol/L, FE_{Na} may be $> 2\%$	Normal or red blood cells, white blood cells and crystals

FE_{Na} , fractional excretion of sodium; FE_{urea} , fractional excretion of urea; HUS, hemolytic-uremic syndrome; TTP, thrombotic thrombocytopenic purpura; U_{Na} , urine sodium concentration.

involving the kidney. A urine dipstick test that is positive for red blood cells in the absence of red blood cells on microscopy suggests the presence of either hemoglobinuria or myoglobinuria. Heavy crystalluria suggests the presence of crystalline intratubular obstruction with uric acid crystals suggestive of tumor lysis syndrome, oxalate crystals suggestive of ethylene glycol ingestion, and drug crystals associated with drug-induced nephropathy. The presence of heavy proteinuria with negative or only trace protein by dipstick and only minimal albuminuria suggests the presence of light chains in the urine and a diagnosis of acute myeloma kidney.

RADIOLOGIC IMAGING

Imaging of the kidneys and bladder is required for the diagnosis of obstructive kidney disease.^{144,145} The usual initial test is a renal ultrasound. Rarely, the presence of extensive retroperitoneal disease may give a false-negative ultrasonographic result (so-called nondilated obstructive uropathy).¹⁴⁶ Non-contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI) may be helpful in this setting to delineate the presence or absence of retroperitoneal disease. Non-contrast-enhanced CT scanning is also the initial diagnostic test of choice for the evaluation of obstruction from nephrolithiasis. Intravenous radiocontrast administration should be avoided in patients with AKI due to the risk of worsening kidney function from superimposed contrast nephropathy. Similarly, the use of gadolinium-containing contrast agents is contraindicated in AKI due to the risk of inducing nephrogenic systemic fibrosis.^{147,148} Cystoscopic retrograde or percutaneous antegrade pyelography is occasionally necessary both diagnostically and for the treatment of obstructive disease. Imaging studies may also be helpful for the diagnosis of renovascular disease, renal vein thrombosis, and renal infarction.

OTHER LABORATORY TESTING

A careful review of other standard laboratory tests may be helpful in identifying the cause of AKI. A markedly elevated creatinine phosphokinase (CPK) suggests the diagnosis of rhabdomyolysis. A disproportionately elevated serum potassium, phosphate, and uric acid accompanied by elevated lactate dehydrogenase (LDH) suggests diffuse tissue destruction, as occurs in AKI complicating both rhabdomyolysis and the tumor lysis syndrome. An elevated LDH may also be seen in patients with renal infarction.⁸⁹ Findings on the hemogram and peripheral blood smear may also be informative. The presence of anemia and rouleaux formation, particularly if accompanied by an increase in serum globulins and hypercalcemia may suggest the presence of multiple myeloma. Eosinophilia is associated with allergic interstitial nephritis, atheroembolic disease and polyarteritis nodosa. Thrombocytopenia and microangiopathic hemolytic anemia may be seen in vasculitis; hemolytic-uremic syndrome; thrombotic thrombocytopenic purpura; disseminated intravascular coagulation, which is often seen in association with sepsis; scleroderma renal crisis; and malignant hypertension. If a glomerulonephritis or vasculitis is suspected, specific serologic testing may be indicated, including serum complement levels, antinuclear antibody (ANA),

anti-double-stranded DNA, antineutrophilic cytoplasmic antibodies (ANCA), anti-glomerular basement membrane (anti-GBM) antibodies, hepatitis B and C virus, rheumatoid factor, and serum cryoglobulins.

NOVEL BIOMARKERS

A number of novel biomarkers, including kidney injury molecule-1 (KIM-1),^{108,109} neutrophil gelatinase-associated lipocalin (NGAL),¹¹⁰⁻¹¹⁶ interleukin 18 (IL-18),¹¹⁴⁻¹¹⁸ liver fatty acid binding protein (L-FABP),^{40,119} and α - and π -glutathione-S-transferase (GST),^{120,121} have been proposed both as a means for early diagnosis of AKI and as a means for differentiating between prerenal and intrinsic causes of AKI. For example, elevations in NGAL have been shown to predict progression of AKI and ultimate need for renal replacement therapy.¹⁴⁹ However, these biomarkers may also be increased in prerenal disease.⁴⁰ At present, the optimal role of these biomarkers in the evaluation of patients with AKI remains uncertain.

RENAL BIOPSY

Renal biopsy is usually reserved for patients in whom prerenal and obstructive causes of AKI have been excluded and the cause of intrinsic AKI remains unclear.^{150,151} Kidney biopsy is particularly useful for the diagnosis of acute glomerulonephritis, vasculitis, and interstitial nephritis, in which definitive diagnosis is required to guide specific therapy with corticosteroids or immunosuppression. The precise indications for a kidney biopsy in the critically ill patient with AKI are not established. Factors such as the lack of clinical or laboratory clues to the cause of the AKI and the presence of features atypical for ATN (such as heavy proteinuria, dysmorphic red blood cells, and red blood cell casts on urinalysis, or the presence of an unexplained pulmonary-renal syndrome) are reasonable indications for proceeding with a biopsy. The primary risk of kidney biopsy is postbiopsy hemorrhage, with increased risk seen in patients with poorly controlled hypertension, coagulopathy, thrombocytopenia, or uremic platelet dysfunction. Experience has demonstrated, however, that kidney biopsy can be safely performed even in ICU patients undergoing mechanical ventilation.¹⁵²

PREVENTION

As previously described, the major risk factors predisposing to the development of AKI in the ICU setting are decreased renal perfusion, nephrotoxicity from medications and contrast media, and septic shock. Thus, efforts to prevent AKI should be directed at maintaining renal perfusion and avoiding hypotension, selecting and dosing medications to minimize the risk of nephrotoxicity, and preventing nosocomial infections.

MAINTENANCE OF RENAL PERFUSION

Intravascular volume expansion for the maintenance of renal perfusion in high-risk patients is one of the simplest interventions for the prevention of AKI. Volume

administration has been shown to decrease the risk of AKI in a variety of clinical settings including myoglobinuric and hemoglobinuric AKI,¹⁵³⁻¹⁵⁵ radiocontrast nephropathy,^{156,157} and aminoglycoside- and amphotericin-associated nephrotoxicity.^{158,159} Fluid administration has also been shown to decrease the risk of intratubular obstruction from crystal deposition in the tumor lysis syndrome¹⁶⁰ and in the drug-induced crystalline nephropathies.^{95,96} The role of volume administration for the prevention of AKI in sepsis is more challenging.^{61,161} Septic shock is associated with relative vasodilation and increased vascular permeability leading to sequestration of extracellular fluid volume and renal hypoperfusion. In addition, although sepsis is a hyperdynamic state with increased cardiac output, relative myocardial depression is common. The use of goal-directed fluid resuscitation in early sepsis has been advocated, and data suggest a modest reduction in the incidence of AKI.^{162,163} However, fluid resuscitation in this setting is not without risk. Although fluid challenges can result in stabilization and improvement in renal function, persistent fluid challenges should be avoided if either no improvement in kidney function or worsening oxygenation from pulmonary vascular congestion occurs. The selection of fluid has also been subject to considerable scrutiny. The use of synthetic colloids as compared to saline is thought to provide greater expansion of the intravascular space. Recent studies, however have suggested that hydroxyethyl starch is associated with an increased risk of AKI and mortality in critically ill patients, and in particular, in patients with severe sepsis.¹⁶⁴⁻¹⁶⁷

The role of renal vasodilators, including dopamine and fenoldopam, to maintain renal perfusion has also been advocated in the past. Multiple studies have demonstrated, however, that this strategy does not reduce the risk of AKI.¹⁶⁸⁻¹⁷⁷ Thus the use of these agents cannot be advocated for the prevention of AKI.

AVOIDANCE OF NEPHROTOXICITY

Many of the medications used for the treatment of critically ill patients carry a risk for nephrotoxicity, with pharmacologic agent-associated nephrotoxicity accounting for approximately one quarter of ICU-associated AKI.^{19,46,79,178} Common nephrotoxins include radiocontrast agents, ACEIs, ARBs, direct renin inhibitors, NSAIDs, and aminoglycosides. Other nephrotoxins that are less frequently encountered or are used in highly selective populations include amphotericin B, pentamidine, vancomycin, colistin, cisplatin, and high doses of methotrexate and acyclovir, intravenous immunoglobulin (IVIG), and nucleoside inhibitors.

Several general principles are involved in avoiding drug-induced nephrotoxicity: (1) recognizing the nephrotoxic potential of selected pharmacologic agents; (2) knowing which patient populations are at high risk; (3) weighing the risk-benefit ratio for use of a potential nephrotoxin in each patient; (4) considering the use of alternative non-nephrotoxic agents; (5) using the smallest effective dose of each potential nephrotoxin for the briefest interval possible; (6) monitoring blood levels of nephrotoxic agents, when available; (7) frequently monitoring kidney function; and (8) having a surveillance system for early detection of drug-related nephrotoxicity (Box 55.4).

Box 55.4 Strategies to Minimize Risk of Nephrotoxic Acute Kidney Injury

- Recognize agents with nephrotoxic potential.
- Recognize high-risk patients.
- Avoid nephrotoxic agents if possible.
- If nephrotoxic agent must be used, use the smallest dose necessary.
- Use the least nephrotoxic formulation.
- Monitor drug levels if available.
- Monitor kidney function.
- Maintain volume-expanded state.
- Avoid concomitant administration of other nephrotoxic agents.
- Use automatic stop orders to force periodic reevaluation of need for nephrotoxin.

Risk factors for aminoglycoside nephrotoxicity include the use of high doses, prolonged duration of therapy, decreased renal perfusion, associated liver disease, concomitant nephrotoxin administration, and possibly, advanced age.^{80,81,83} In patients in whom aminoglycoside therapy is considered, clear goals for the use of the agent and plans for duration of therapy need to be formulated to ensure that treatment duration is no longer than absolutely necessary. Euvolemia and adequate renal perfusion should be maintained, concomitant nephrotoxins should be avoided, dosage should be adjusted based on measurement of plasma levels, and kidney function should be monitored on an ongoing basis. The observation that antimicrobial efficacy of aminoglycosides persists even after the drug levels in the blood have fallen below the minimal bactericidal concentration (postantibiotic killing) has led to the development of once-daily dosing regimens that provide higher peak levels but with less frequent dosing.^{81,179-181} These regimens have been shown to result in rates of bacteriologic cure comparable with standard dosing regimens but are associated with lower rates of AKI.

Vancomycin is an antibiotic that has been associated with an increasing incidence of AKI as a result of both increased utilization and the targeting of higher drug levels.^{182,183} Although many cases of putative vancomycin nephrotoxicity merely represent elevated drug levels due to decreased renal clearance, the use of higher doses has been associated with an increase in nephrotoxicity. Adjustment of dosing in response to close monitoring of blood levels, especially in patients with fluctuating kidney function, should minimize the risk of drug-induced AKI. Nephrotoxicity of drugs may be reduced through changes in formulation. For example, the use of lipid emulsions of amphotericin B is associated with reduced risk of amphotericin-induced AKI.¹⁸⁴

NSAIDs often induce AKI by causing renal vasoconstriction, especially in settings where the renal circulation is dependent on angiotensin.^{45,185} Less frequently, NSAIDs cause an interstitial nephritis, often accompanied by glomerular involvement with heavy proteinuria. Patients at risk for the development of NSAID-induced AKI include individuals with volume depletion, shock, hypotension, cardiac or liver disease, advanced age, and underlying CKD. Any

patient with one or more of these risk factors should be carefully monitored for changes in kidney function associated with NSAID therapy. The same patient population at risk for NSAID-induced AKI is also at greatest risk for an abrupt decrease in kidney function following initiation or adjustment in the dose of ACEIs, ARBs, or direct renin inhibitors.⁴⁸ In addition, patients with bilateral renal artery stenosis or unilateral renal artery stenosis with a nonfunctional or absent contralateral kidney are also at increased risk for AKI with inhibition of the renin-angiotensin-aldosterone system.

PREVENTION OF CONTRAST-INDUCED ACUTE KIDNEY INJURY

Beyond the preceding general interventions, prevention of AKI requires that the insult to the kidney be timed in such a fashion that preventive strategies can be implemented prospectively. Contrast-induced AKI (CI-AKI) following the administration of iodinated radiocontrast media represents one of these few situations. Cardiac surgery represents another such setting; however, other than minimizing time on cardiopulmonary bypass and avoiding intraoperative and postoperative decreases in renal perfusion, there are no proven strategies for the prevention of cardiac surgery-associated AKI.

Risk factors for CI-AKI are well defined, with the single most important risk factor being preexisting CKD. In patients with normal kidney function, the risk of CI-AKI is much lower than 1% but increases in a graded fashion with severity of CKD.^{186,187} Other risk factors include increasing age, diabetes mellitus, congestive heart failure, volume depletion, and concomitant NSAID use.⁸⁵ Utilization of alternative imaging modalities is the most effective means of preventing CI-AKI; however, when that is not possible strategies should be implemented to minimize the risk of nephrotoxicity. The primary intervention for prevention of CI-AKI is administration of isotonic intravenous fluids prior to and following the administration of contrast medium,^{157,188} although the optimal composition and rate of fluid administration are not known. Studies comparing the relative benefits of isotonic saline and isotonic sodium bicarbonate have yielded conflicting results.¹⁸⁹⁻¹⁹² In hospitalized patients the administration of either isotonic saline or isotonic sodium bicarbonate at a rate of 1 mL/kg/hour for 12 hours prior to and 12 hours following the procedure is recommended³; however, alternative regimens involving more rapid fluid administration for a shorter duration may be equally efficacious.

Multiple pharmacologic agents have been evaluated, but most of them are not beneficial for preventing CI-AKI, including mannitol, furosemide, dopamine, fenoldopam, and calcium channel blockers.^{176,193-197} Trials of other agents, including natriuretic peptides, aminophylline and theophylline, statins, and ascorbic acid have yielded conflicting results.¹⁹⁸⁻²⁰⁷ N-acetylcysteine (NAC), an antioxidant with vasodilatory properties, has been evaluated for the prevention of CI-AKI in multiple clinical trials. The rationale for the use of NAC relates to its capacity to scavenge reactive oxygen species, reduce the depletion of glutathione, and stimulate the production of vasodilatory

mediators including nitric oxide.^{208,209} These clinical trials of both oral and intravenous NAC have yielded contradictory findings.²¹⁰⁻²¹⁸ Although it is uncertain whether NAC is beneficial in preventing CI-AKI, in its oral form it is both safe and inexpensive. For this reason, some, but not all, practice guidelines have recommended its use, with the important caveat that it should not be employed in lieu of intravenous fluids for the prevention of CI-AKI.^{3,219}

Renal replacement therapies for the prevention of CI-AKI are ineffective, and the use of “prophylactic” hemodialysis has been associated with harm.²²⁰⁻²²² Although hemofiltration has been suggested to decrease the postprocedural increase in serum creatinine, the interpretation of these studies is confounded by the lowering of serum creatinine by the intervention.^{223,224} Given the risks associated with intravenous line placement along with a lack of clear benefit, the use of dialysis or hemofiltration to prevent CI-AKI is not recommended.²²⁵

MANAGEMENT OF ESTABLISHED ACUTE KIDNEY INJURY

There is no specific management for the vast majority of patients with established AKI. Patients with prerenal azotemia should have intravascular volume deficits corrected and cardiac function optimized. Patients with hepatorenal syndrome may respond to vasoconstrictor therapy to reverse the splanchnic and peripheral vasodilation that underlies the development of the syndrome.^{226,227} Abdominal compartment syndrome is treated with abdominal decompression.^{53,54} Obstructive (postrenal) kidney disease is treated by mechanical relief of obstruction. The primary management of acute interstitial nephritis is discontinuation of the inciting agent; in patients with persistent AKI there may be a role for treatment with glucocorticoids. The treatment of AKI developing as a result of acute glomerulonephritis or renal involvement by vasculitis is dependent upon the precise cause and may include glucocorticoids and immunomodulatory therapy. Once AKI has developed and treatable or reversible causes have been excluded, the general therapeutic approach outlined in [Box 55.5](#) is followed. Optimization of extracellular fluid volume status, cardiac index,

Box 55.5 General Therapeutic Approach to Established Acute Kidney Injury

- Correct prerenal factors and maintain euvolemic state.
- Attempt to establish a urine output if the patient remains oliguric despite correction of prerenal factors and exclusion of obstructive uropathy.
- Monitor for clinical and biochemical complications.
- Carefully monitor all drug therapy, dose-reducing medications for reduced glomerular filtration rate (GFR).
- Provide adequate nutrition.
- Reduce risk for infection.
- Use renal replacement therapy when indicated.

and maintenance of perfusion and oxygenation of vital organs are considered first.

MANAGEMENT OF VOLUME STATUS

Once volume status and cardiac output have been optimized, if the patient remains oliguric the use of a short trial of diuretics to establish urine output can be considered. Although nonoliguric forms of ATN are associated with significantly lower risk of morbidity and mortality than oliguric forms, the primary rationale for a trial of diuretic therapy is to facilitate volume management.¹²² There is no evidence that conversion of ATN from an oliguric to a nonoliguric form alters risk of morbidity and mortality,^{228,229} and if a diuretic response is not seen after one or two doses, diuretic agents should be discontinued. The utility of diuretic therapy is supported by a *post hoc* analysis of data from 306 patients from the Acute Respiratory Distress Syndrome Network's Fluid and Catheter Treatment Trial (FACTT) who developed AKI.²³⁰ Positive fluid balance after development of AKI was associated with increased mortality rate; higher doses of furosemide had a protective effect on mortality rate, although this effect was attenuated after adjustment for fluid balance. Thus, the benefit of diuretics was thought to be mediated by fluid balance. No threshold dose of furosemide was observed above which the mortality rate increased.

In contrast to the use of diuretics, the use of renal vasodilators, including dopamine, fenoldopam, and atrial natriuretic peptide (ANP), has not been shown to be beneficial in AKI. Low-dose dopamine increases renal blood flow and to a lesser extent GFR in experimental animals and in healthy human volunteers and inhibits sodium reabsorption in the proximal tubule. However, in prospective clinical trials, low-dose dopamine has not been demonstrated to prevent or alter the course of ischemic or nephrotoxic ATN.¹⁶⁸⁻¹⁷⁵ In a meta-analysis, the use of low-dose dopamine was associated with a transient increase in urine output on day 1 but had no impact on the development or progression of AKI, need for renal replacement therapy, or mortality rate.¹⁷⁴ Thus, the use of low-dose dopamine in the treatment of AKI is not justified.^{231,232} Fenoldopam is a selective dopamine (DA1) receptor agonist.²³³ In a randomized controlled trial of ICU patients with early ATN, fenoldopam failed to reduce mortality rate or the need for renal replacement therapy.¹⁷⁷ Similarly, anaritide, a synthetic analog of ANP, failed to show clinically significant improvement in dialysis-free survival rate or overall mortality rate in patients with ATN.²³⁴ Although there was an improvement in dialysis-free survival rate in the subset of patients who were oliguric, this benefit was not confirmed in a subsequent study.²³⁵

PREVENTING, MONITORING, AND TREATING COMPLICATIONS

AKI is associated with the development of numerous electrolyte and acid-base disturbances, including most commonly hyperkalemia, hyponatremia, hyperphosphatemia, hypo- and (less commonly) hypercalcemia, hypermagnesemia, hyperuricemia, and metabolic acidosis. In

addition, AKI is associated with anemia, bleeding diatheses, increased risk of infections, and dysfunction of other organ systems, including cardiovascular dysfunction, respiratory failure, gastrointestinal complications, and neurologic disturbances.

A detailed discussion of these complications can be found in the online supplement at www.expertconsult.com.

MEDICATION DOSING CONSIDERATIONS

Most pharmacologic agents are eliminated, at least in part, by the kidneys. Thus, use of standard doses and dosing intervals of many pharmacologic agents in patients with AKI can lead to accumulation of active drug or metabolites, with subsequent drug-induced morbidity and death. To avoid medication-induced toxicity in AKI, scrutiny of the medication list is essential. All medications not essential for care should be eliminated. A thorough understanding of the pathways of drug metabolism and elimination and the potential side effects of each drug used is mandatory. Excellent, up-to-date resources of this information are readily available.²⁶⁵ Careful monitoring of clinical and biochemical parameters and drug levels is indicated, especially for agents with narrow therapeutic indices that are eliminated by the kidneys. In addition, further dosage adjustments may be required when renal replacement therapy is provided, especially for antibiotics to ensure that adequate therapeutic levels are achieved.

NUTRITIONAL CONSIDERATIONS

Nutritional support for patients with AKI must be considered in the overall context of associated comorbid conditions and other aspects of the management of critically ill patients.²⁶⁶⁻²⁶⁹ The optimal nutritional support in critically ill patients with AKI is often influenced more by the nature of underlying illness and the type and frequency of renal replacement therapy rather than the AKI per se. The presence of oliguria and of high protein catabolic rates becomes an important consideration in the nutritional management of patients with severe ICU-associated AKI.²⁶⁶⁻²⁶⁹ When possible, nutrition should be provided via the enteral route, as even small amounts of luminal nutrition help maintain intestinal integrity and decrease the risk of bacterial translocation. However, enteral nutrition is often insufficient to meet patient requirements and parenteral nutrition is often necessary. Caloric intake should generally be 25 to 30 kcal/kg/day and even in hypercatabolic patients, energy intake should not exceed 35 kcal/kg/day.²⁷⁰ In noncatabolic patients, a protein intake of 1 to 1.3 g/kg/day is generally sufficient to achieve positive nitrogen balance. In hypercatabolic patients and patients receiving continuous renal replacement therapy, protein catabolic rates may reach 1.5 to 1.7 g/kg/day and higher protein intakes are ineffective in achieving positive nitrogen balance.²⁷¹ Current recommendations are that catabolic patients with AKI should receive 1.2 to 1.5 g/kg of protein and amino acids on a daily basis, even after adjusting for amino acid losses that occur during renal replacement therapy.^{269,272} Careful attention must be paid to fluid volume and electrolyte content of nutritional formulations so as to minimize the risk of

HYPERKALEMIA

Hyperkalemia is an ever-present threat in patients with AKI. Plasma potassium concentrations of more than 5 mmol/L occur in up to 50% and more than 6 mmol/L in up to 30% of patients with AKI.²³⁶ Hyperkalemia occurs because of continued accumulation of potassium in extracellular fluid associated with diminished ability of the kidney to eliminate potassium. Usually the potassium concentration increases by approximately 0.2 to 0.4 mmol/L/day. Greater increases occur in the presence of continued potassium intake (e.g., intravenous fluids, blood products, and dietary sources) or continued release of potassium from body stores (e.g., hemolysis, tumor lysis, and rhabdomyolysis).

Hyperkalemia increases the resting electrical membrane potential of myocardial conducting tissue. As the resting potential nears the threshold potential, electrocardiographic (ECG) changes (loss of P waves, peaked T waves, bradycardia, left-axis deviation, left bundle branch block, wide QRS complex) can occur.²³⁷ These ECG changes are seen most prominently in the anterior precordial (V₂ to V₄) leads. With severe hyperkalemia, a sine wave and ventricular fibrillation or asystole can result.

The therapeutic approach for treating hyperkalemia in AKI are listed in Table 55.E1. Mild elevations (<5.5 mmol/L without ECG changes) can best be treated by withdrawing all exogenous sources of potassium and continuing close ECG and laboratory follow-up. If potassium concentration increases to more than 6.0 mmol/L, and especially if ECG changes are present, then more active therapy is indicated (see Table 55.E1). Intravenous calcium is immediately effective for hyperkalemic emergencies, stabilizing excitable membranes, but does not lower the serum potassium concentration. While calcium is indicated when serious ECG manifestations (more than peaked T waves) are present, calcium administration is not appropriate in the absence of these changes. Administration of intravenous calcium in

patients with significant hyperphosphatemia may cause precipitation of calcium and phosphate in vascular and soft tissues. Intravenous insulin and β -adrenergic agonists (inhaled albuterol) will cause potassium to shift into the intracellular compartment, lowering the extracellular potassium concentration.^{238,239} Although sodium bicarbonate also drives potassium from the extracellular fluid into cells, the slow time course of this response makes intravenous bicarbonate ineffective in the acute treatment of hyperkalemia in the absence of severe acidemia.^{239,240} The ultimate treatment of hyperkalemia is increased excretion. In AKI, the use of diuretics to increase renal potassium excretion is unlikely to be effective. Therapies therefore include the use of gastrointestinal sodium polystyrene sulfonate, and potassium-binding resin to increase gastrointestinal potassium losses or the initiation of dialysis.

HYPONATREMIA

Hyponatremia from excess free water administration in the presence of impaired renal ability to excrete water is common in AKI.²⁴¹ This hyponatremia is generally mild and asymptomatic, although a marked reduction in serum sodium concentration that occurs quickly can lead to confusion, disorientation, and seizures. Treatment consists of water restriction. In unusual circumstances, dialytic therapy may be necessary.

CALCIUM, PHOSPHORUS, AND MAGNESIUM DISORDERS

Hypocalcemia and hyperphosphatemia are nearly uniform occurrences in AKI.^{236,242,243} The hyperphosphatemia is caused primarily by decreased urinary excretion of phosphorus with continued release of phosphorus from intracellular stores. Usually the increase in serum phosphorus is modest, with peak values in the 4- to 6-mg/dL range. In the presence of diffuse tissue injury (i.e., rhabdomyolysis, tumor lysis syndrome), marked (>9 mg/dL) hyperphosphatemia can occur. Significant hyperphosphatemia can lead to hypohypocalcemia and tissue deposition of calcium phosphate salts. Therefore, monitoring of serum phosphorus concentration is necessary. Mild elevations can be treated with oral phosphate binders such as aluminum hydroxide, calcium salts, sevelamer, or lanthanum carbonate. More marked elevations are usually treated with dialysis.

Hypocalcemia in AKI is usually modest, with values rarely falling below 6 to 7 mg/dL.^{236,242,243} Hypocalcemia is rarely of clinical significance because the ionized calcium is maintained by metabolic acidemia. However, aggressive correction of acidemia can precipitate tetany and other symptoms of hypocalcemia. The cause of the hypocalcemia is multifactorial. It may be partially attributed to hyperphosphatemia with a presumed reciprocal lowering of calcium as a result of calcium phosphate tissue precipitation. The most significant hypocalcemia usually occurs in the presence of profound hyperphosphatemia. Other factors can also contribute to hypocalcemia of AKI. Despite very high parathyroid hormone levels in AKI, parathyroid hormone does not mobilize calcium from bone as it does in normal individuals. This skeletal resistance to parathyroid hormone may result in part from an impaired ability of the diseased kidney to render vitamin D active by converting the inactive

Table 55.E1 Treatment of Hyperkalemia in Acute Kidney Injury

Modality	Onset of Action	Duration of Action
Membrane Stabilization		
Intravenous calcium	Immediate	5-10 minutes
Intracellular Shift of Potassium		
Intravenous insulin (given with glucose in patients who are not hyperglycemic)	15-30 minutes	1-2 hours
Inhaled albuterol	30-60 minutes	1-2 hours
Removal of Potassium		
Gastrointestinal potassium exchange resin (sodium polystyrene sulfonate)	1-4 hours	Hours
Hemodialysis	1-4 hours	Hours

25-(OH)-vitamin D to the active 1,25-(OH)₂-vitamin D. Thus, low levels of the active form of vitamin D are frequently seen in patients with AKI. Usually, lowering serum phosphate concentration when appropriate is the only treatment needed to improve the serum calcium concentration in AKI. If symptoms of hypocalcemia are present, the infusion of calcium gluconate to alleviate these symptoms may be indicated.

Rarely, hypercalcemia complicates the course of AKI. This hypercalcemia usually occurs during the diuretic phase of rhabdomyolysis-associated AKI.²⁴³ The mechanisms of this hypercalcemia are unclear. Mobilization of calcium salts deposited in damaged tissue combined with normalization of 1,25-(OH)₂-vitamin D levels and loss of skeletal resistance to parathyroid hormone may all contribute. This hypercalcemia can be treated by dialysis with low-calcium dialysate if necessary.

Hypermagnesemia of modest degree (2 to 4 mg/dL) is frequently seen in AKI.^{236,242} This degree of hypermagnesemia is almost always asymptomatic. However, significant symptomatic hypermagnesemia can occur if magnesium-containing antacids are given to patients with kidney failure.

HYPERURICEMIA

Hyperuricemia from continued production of uric acid concomitant with decreased renal excretion of uric acid usually accompanies AKI. The usual peak uric acid concentration is 9 to 10 mg/dL. Much higher levels of uric acid are seen when AKI accompanies diffuse cell injury, as in rhabdomyolysis, in which case the mean uric acid concentration averages 14 to 15 mg/dL and not infrequently exceeds 20 mg/dL.^{86,244} Despite high concentrations of uric acid in the blood, there is little evidence that this temporary hyperuricemia results in harm. The GFR in AKI is usually so low that little uric acid is filtered, and thus intratubular precipitation does not occur. Acute gout is rarely seen in patients with AKI, despite frequent hyperuricemia. Thus, the secondary hyperuricemia of AKI is usually not specifically treated. One setting in which hyperuricemia is harmful is acute uric acid nephropathy, which typically occurs after therapy for bulky tumors when there was no pretreatment with rasburicase (recombinant uricase) or xanthine oxidase inhibitors (allopurinol) and aggressive hydration.²⁴⁴⁻²⁴⁷ Almost always the plasma uric acid concentration exceeds 20 mg/dL. Sometimes it is difficult to distinguish whether hyperuricemia is a cause or a consequence of AKI. Hyperuricemia as a cause of AKI usually requires an acute elevation of plasma uric acid to more than 20 mg/dL and results in oligoanuric AKI with abundant uric acid crystals in the urine. Measurement of the urinary uric acid/creatinine ratio on a random specimen may also help distinguish between hyperuricemia caused by overproduction and impaired excretion. This ratio is typically greater than 1.0 when uric acid production is increased and less than 0.75 in normal individuals and patients with impaired kidney function.²⁴⁸

METABOLIC ACIDOSIS

Metabolic acidosis, from continued production of nonvolatile acid combined with inability of the injured kidney to generate new bicarbonate, occurs frequently in AKI. The decline in plasma bicarbonate concentration that occurs from metabolic acidosis in AKI is usually about 0.5 to

1 mmol/L/day.¹²² Approximately 20% of AKI patients develop a bicarbonate concentration of less than 15 mmol/L. This metabolic acidosis is usually associated with an increase in anion gap. In some cases of rhabdomyolysis-associated AKI, a greater anion gap will be seen.⁸⁶ The mild nature of the metabolic acidosis that can be attributed to AKI per se usually does not require therapy. However, AKI often occurs in a setting in which excess lactic acid accumulates and following ingestions (e.g., ethylene glycol) that result in marked acidosis.

ANEMIA

Some degree of anemia usually occurs with AKI. In general, with uncomplicated severe AKI, the hemoglobin concentration slowly declines to a nadir of about 10 to 12 g/dL, where it remains until renal function improves. The mechanisms underlying the anemia are related, at least in part, to impaired red blood cell production caused by deficiency of erythropoietin, which is synthesized by the kidney.^{249,250} In a recent study of 20 patients with AKI, radioimmunoassay values for erythropoietin were very low. Several weeks and in some cases months were required for normalization of serum erythropoietin in AKI patients.²⁵⁰ In one patient with AKI, exogenous recombinant erythropoietin resulted in a brisk reticulocytosis and amelioration of anemia, suggesting a lack of endogenous inhibitors of erythropoiesis in AKI.²⁵⁰ In other studies, erythropoietin use has not been associated with either a decrease in transfusion requirements or with enhanced renal recovery when given in the context of AKI.²⁵¹ Other factors often contribute to the anemia of AKI including frequent blood drawing for laboratory testing, gastrointestinal blood loss, loss of blood during procedures, marrow suppression caused by medications, and loss of red blood cells in dialyzers. Of note, several disease processes that can produce AKI may have prominent hematologic abnormalities such as anemia (plasma cell dyscrasia); eosinophilia (allergic interstitial nephritis, polyarteritis nodosa, atheroembolic disease); and thrombocytopenia (systemic lupus erythematosus, thrombotic thrombocytopenia purpura, hemolytic-uremia syndrome, malignant hypertension, disseminated intravascular coagulation). In general the anemia of AKI develops slowly and is usually well tolerated. Thus, not only is specific treatment often not indicated, but it is not likely to be effective.²⁵⁰⁻²⁵²

BLEEDING

Clinically significant bleeding may complicate the course of 10% to 30% of patients with AKI. In a study of patients developing AKI after contrast-enhanced imaging studies, 15% of patients with mild CI-AKI had a bleeding disorder before they developed AKI, and this increased to 27% after the development of AKI.²⁵³ In a large multicenter study, 32% to 42% of patients with AKI had some degree of thrombocytopenia, and 13% to 27% had a coagulopathy.²³⁴ Usually the coagulopathy results from associated diseases (e.g., liver disease, sepsis, disseminated intravascular coagulation) or treatments (e.g., multiple transfusions). When AKI results from rhabdomyolysis, particularly in association with cocaine abuse, thrombocytopenia and disseminated intravascular coagulopathy are especially likely.²⁵⁴ The AKI state per se may result in a functional defect in platelets, leading to prolongation of the bleeding time and perhaps contributing

to clinically relevant coagulopathy.²⁵⁵⁻²⁵⁹ Several therapeutic maneuvers can improve the bleeding time and the coagulopathy that is occasionally seen in AKI. Intravenous administration of desmopressin is the easiest, safest method of shortening the bleeding time.²⁵⁶ Unfortunately, the effect of desmopressin is short-lived, and patients rapidly become tachyphylactic to repetitive doses. Cryoprecipitate also shortens the bleeding time in renal failure states.²⁵⁵ Again, the duration is relatively brief. The precise mechanisms whereby desmopressin and cryoprecipitate shorten bleeding time in renal failure are not known. Most data suggest that these agents result in induction (desmopressin) or infusion (cryoprecipitate) of large, multimeric forms of factor VIII–von Willebrand factor aggregates, which enhances binding of platelets to endothelial surfaces.²⁵⁹ Repeated doses of conjugated estrogen can result in prolonged normalization of the bleeding time in uremia, although the mechanism is not clear.²⁵⁸ Restoration of the hemoglobin concentration toward normal also shortens the bleeding time in uremia.²⁵⁷ Finally, dialysis may shorten the bleeding time, but the magnitude of effect and amount of dialysis required to achieve improvement are highly variable.

INFECTIONS

Infectious complications are among the most common causes of death in AKI. For example, in an older study infections were judged to be the primary cause of death in 30% to 50% of seriously ill patients with AKI.²⁶⁰ In most studies of ICU patients with AKI, more than 50% to 75% of patients experience at least one infectious complication. In a study of CI-AKI, the frequency of sepsis before and after the development of AKI was 22% and 45%, respectively.²⁵³ Common sources of infections are operative sites, intravascular access lines, the urinary tract, and the lungs. Because of the frequent presence of infection, most ICU patients with AKI are treated with multiple antibiotics for several days. Clinical signs such as fever and leukocytosis are often less pronounced when infection is present in patients with AKI compared with those with normal renal function.²⁶¹ To reduce the risk of infection, efforts should be directed at possible prevention of nosocomial infections by removing invasive lines and bladder catheters as soon as possible. Strict aseptic technique and clinical monitoring of line sites are necessary. When infection is suspected, prompt culturing and selective use of antimicrobial agents are indicated.

CARDIOVASCULAR COMPLICATIONS

Because most patients with ICU-associated AKI are severely ill, hemodynamic instability is commonly encountered. In an oliguric patient with AKI, volume overload with resultant pulmonary edema, peripheral edema, and hypertension is an ever-present threat to well-being and survival. Although pulmonary edema is usually caused by positive fluid balance, decreased colloid oncotic pressure caused by hypoalbuminemia and perhaps increased pulmonary capillary permeability can contribute. Volume overload has been shown to be an independent risk factor for death in AKI.^{262,263} Also, many patients at high risk for developing AKI have underlying chronic heart disease. Careful serial clinical evaluation and monitoring of volume status, body weight, oxygenation, hemodynamic measurements, and chest radiographs are often necessary to help assess volume status in patients with

AKI. Several cardiovascular complications such as myocardial infarction; arrhythmias; and, rarely, pericarditis can complicate the course of patients with AKI. In a multicenter study, 22% to 29% of patients with AKI experienced cardiac arrhythmias requiring therapy and 13% to 19% had evidence of myocardial ischemia.²³⁴ The development of any of these cardiovascular complications is a major risk factor for adverse outcomes from AKI. Treatment of fluid overload in the setting of AKI depends on the degree of renal impairment. If it is mild nonoliguric AKI, loop diuretics are often effective in reducing positive fluid balance. If the patient has severe oliguric AKI, some type of extracorporeal method of removing volume is necessary.

PULMONARY COMPLICATIONS

In addition to volume overload, several other processes can involve the lungs in patients with AKI. Thus aspiration, infection, and adult respiratory distress syndrome (ARDS) all occur commonly in patients with AKI. Patients with AKI have about a 30% chance of developing an infiltrate on chest radiograph.¹²² In many series of patients with severe AKI, up to 50% also have respiratory failure sufficient to require mechanical ventilation. In a clinical trial of ANP for the treatment of AKI, 48% to 55% of AKI patients were intubated and ventilated at the time they developed AKI; In the Acute Renal Failure Trial Network (ATN) study, More than 80% of patients were on mechanical ventilation at the time of initiation of renal replacement therapy.¹²⁵ Mechanical ventilation is clearly a significant, independent factor associated with increased mortality in patients with AKI.²⁴ Several disease processes can cause simultaneous renal and respiratory failure and include acute glomerulonephritis with volume overload, Goodpasture's syndrome, granulomatosis with polyangiitis or microscopic polyangiitis, systemic lupus erythematosus, polyarteritis nodosa, cryoglobulinemia, and renal vein thrombosis with pulmonary emboli.

GASTROINTESTINAL COMPLICATIONS

Anorexia, nausea, and vomiting are symptoms commonly seen in patients with advanced renal failure. In many series, gastrointestinal hemorrhage, often ascribed to stress gastritis or ulcers, has been reported to occur in 5% to 30% of patients with AKI. Usually gastrointestinal hemorrhage is loosely defined, relatively mild, and easily controlled, but on occasion it may be the cause of death in patients with AKI. Whether the presence of AKI per se is an indication for prophylactic therapy for gastrointestinal bleeding, in the absence of well-recognized indications such as respiratory failure and coagulopathy, is debated.²⁶⁴ Careful prospective studies are necessary for defining the frequency of occurrence and delineating the cause of gastrointestinal hemorrhage in AKI. Also, extreme caution in using magnesium-containing antacids is necessary in the setting of AKI because of the almost exclusive renal route of elimination of magnesium.

Jaundice frequently occurs during the course of AKI in ICU patients. In one prospective study, 28% of patients with ICU-associated AKI were jaundiced at some time during the course of their illness.¹⁹ The etiologic picture in jaundice is usually multifactorial, with passive hepatic congestion, multiple blood transfusions, sepsis, hypotension, and many

medications contributing. A mild increase in amylase also occurs in AKI, and pancreatitis is present in 2% to 10% of patients at the onset of AKI. Because of this amylase elevation, careful clinical assessment and determination of serum lipase levels are often necessary to ascertain whether pancreatitis is present in a patient with AKI.

NEUROLOGIC COMPLICATIONS

Neurologic complications such as confusion, disorientation, lethargy, somnolence, coma, myoclonus, asterixis, and seizures can occur as a result of AKI. In a study of CI-AKI, the frequency of mental status changes increased from 41%

before to 68% after development of AKI.²⁵³ Abnormal consciousness at the time of first visit in patients with AKI was found in 30% of patients in another prospective series.¹⁹ Several causes of neurologic dysfunction are often present in patients with AKI. Most prominent among these are medication-induced encephalopathy, other metabolic disturbances, and primary neurologic disorders such as stroke. Also, several systemic disorders such as vasculitis, endocarditis, thrombotic thrombocytopenic purpura, and malignant hypertension can present with simultaneous AKI and neurologic dysfunction.

exacerbating volume overload or causing serious mineral and electrolyte disturbances.

RENAL REPLACEMENT THERAPY

In patients with severe AKI, renal replacement therapy (RRT) is the cornerstone of supportive management. The goal of renal replacement therapy is to permit the removal of fluids and solutes that accumulate in renal failure, thereby restoring the composition and volume of the extracellular fluids and preventing the complications of uremia. A detailed technical guide to the performance of RRT is beyond the scope of this chapter; the following discussion will provide an overview of RRT with a focus on the key management issues of selection of modality, timing of initiation of therapy, and appropriate intensity of therapy.

MODALITIES OF RENAL REPLACEMENT THERAPY

The available modalities of RRT include conventional intermittent hemodialysis (IHD); the various forms of continuous renal replacement therapy (CRRT) including continuous hemodialysis, continuous hemofiltration, and continuous hemodiafiltration; the hybrid modalities of prolonged intermittent renal replacement therapy (PIRRT; also known as extended duration dialysis²⁷³⁻²⁷⁵ [EDD] or sustained low-efficiency dialysis [SLED])^{276,277}; and peritoneal dialysis.^{278,279}

In IHD and PIRRT, vascular access is generally achieved using large-bore double lumen venous catheters in the internal jugular, subclavian, or femoral veins. Because of concern of causing subclavian stenoses that might impair future angioaccess for chronic dialysis in patients who do not recover kidney function, internal jugular and femoral catheters are generally preferred over subclavian catheters.³ CRRT was initially described using an arteriovenous extracorporeal circuit with inflow through a large-bore arterial catheter and return through a venous catheter. Although these arteriovenous modalities allowed for technical simplicity, they have been largely replaced by pumped venovenous extracorporeal circuits that allow for blood flow rates that are higher and are independent of mean arterial pressure and avoid the complications of prolonged arterial cannulation.²⁷³⁻²⁷⁵

Solute removal during RRT may occur by diffusion down a concentration gradient from the blood, across a semipermeable membrane, into dialysate or by convective transport of solute across the membrane during ultrafiltration. Fluid removal occurs by ultrafiltration, driven by either a hydrostatic or osmotic pressure gradient across the semipermeable dialysis or filtration membrane. In conventional IHD, the patient's blood passes through a semipermeable hemodialyzer countercurrent to the flow of dialysate on the opposite side of the dialysis membrane. The dialysis solution has a composition that approximates the normal electrolyte composition of extracellular fluids. Solutes that accumulate in kidney failure diffuse across the dialysis membrane from blood into dialysate. Fluid removal is achieved by applying a negative pressure across the membrane to permit the desired ultrafiltration rate. Treatment duration and frequency are variable, dictated by the patient's metabolic and volume status.

The CRRTs utilize either diffusive hemodialysis, convective hemofiltration, or a combination of diffusion and convection in continuous hemofiltration. As in intermittent hemodialysis, in continuous hemodialysis blood and dialysate flow in opposite directions on the two sides of the dialysis membrane; solute removal occurs by diffusion down a concentration gradient and ultrafiltration is driven by hydrostatic forces. The ultrafiltration during continuous hemodialysis is set at the level necessary to achieve the desired daily fluid removal. In addition to the duration of therapy, the major difference between intermittent and continuous hemodialysis is the dialysate flow rate. In intermittent hemodialysis, dialysate flow rates (typically 500 to 800 mL/minute) are equal to or greater than blood flow rates, allowing rapid solute clearance. In continuous hemodialysis, the dialysate flow rate (typically 15 to 50 mL/minute) is slow compared to that of the blood, permitting virtual equilibration of low-molecular-weight solutes such as urea between the blood and dialysate. Thus, solute clearance for low-molecular-weight solutes approximates the dialysate flow rate. Although the instantaneous clearance rate during continuous hemodialysis is much lower than during conventional IHD, the daily or weekly clearance is greater due to the longer duration of therapy.

In continuous hemofiltration, a high ultrafiltration rate is generated, and physiologic replacement fluid is administered at a rate equal to the difference between the high ultrafiltration rate and the desired rate of fluid removal. No dialysate is used, solute removal occurs exclusively by convection, and clearance is approximately equal to the ultrafiltration rate. Because the ability of solutes to diffuse across a dialysis membrane is inversely related to their molecular weight, while convective transport is limited primarily by the pore size of the membrane, hemofiltration provides more efficient clearance of higher molecular weight (>500-1500 kDa) solutes. Although it has been proposed that augmented removal of higher molecular weight solutes with hemofiltration as compared to hemodialysis would be of clinical benefit, particularly in patients with sepsis-associated AKI, this has not been borne out in clinical practice. In continuous hemodiafiltration, the dialysate flow of continuous hemodialysis is added to the convective ultrafiltration of continuous hemofiltration. Because of their prolonged duration, the net ultrafiltration rate (the difference between the ultrafiltration rate and infusion of replacement fluid) required to attain the same daily fluid removal is lower with CRRT than with IHD. As a result, CRRT is generally considered to cause less hemodynamic stress than conventional IHD.

Prolonged intermittent renal replacement therapy is a modification of conventional IHD, utilizing lower blood and dialysate flow rates while prolonging the treatment duration to 8 to 16 hours as compared to the usual 3- to 5-hour IHD treatment.^{276,277} As with the continuous therapies, by prolonging the treatment duration and decreasing the rate of net ultrafiltration, the hemodynamic stress on the patient is minimized.

In peritoneal dialysis, dialysate with a high sugar concentration is instilled into the peritoneal membrane. Solute transport occurs by diffusion across the peritoneal membrane down the concentration gradient from blood to dialysate. The high osmolality resulting from the sugar in the

dialysate provides an osmotic gradient for ultrafiltration. Because this is also a continuous therapy it has the same general benefit with regard to hemodynamic stability as CRRT, but the regulation of ultrafiltration is less precise. In addition, the use of glucose as the predominant sugar to generate the osmotic gradient predisposes to the development of hyperglycemia. In addition, the ability to perform peritoneal dialysis may be limited by recent abdominal surgery or intra-abdominal disease.

There has been considerable debate regarding which modality is most appropriate for use in critically ill patients with AKI. Current data suggest that no individual modality of RRT provides either better patient survival or recovery of kidney function.^{3,280} Comparing outcomes between modalities in observational studies is complicated by the fact that patients treated with continuous or extended duration therapy are more likely to have greater severity of illness and be hemodynamically unstable. Not unexpectedly, observational studies have generally found higher unadjusted mortality rates when comparing CRRT to conventional IHD.²⁸¹⁻²⁸⁷ Randomized controlled trials have generally found no survival benefit when comparing continuous and intermittent therapies.²⁸⁸⁻²⁹³ For example, in the Hemodiafe study, the largest of the randomized controlled trials comparing IHD and CRRT, which enrolled 360 patients who were well matched with regard to severity of illness across 21 ICUs in France, there was no difference in either survival or recovery of kidney function.²⁹² Recent systematic reviews and meta-analyses have confirmed the absence of differences in mortality rate or recovery of kidney function across modalities²⁹⁴⁻²⁹⁶ but have suggested that continuous therapy is more effective at attaining negative fluid balance²⁶³ but is more expensive.²⁹⁵ Based on these data, the Kidney Disease Improving Global Outcomes (KDIGO) Clinical Practice Guidelines for Acute Kidney Injury has recommended that continuous and intermittent modalities of RRT be used as complementary therapies, although with the suggestion that CRRT be used preferentially for hemodynamically unstable patients.²⁹⁷ In patients with acute brain injury or increased intracranial pressure, CRRT is associated with better preservation of cerebral perfusion than IHD and is the more appropriate modality of RRT.²⁹⁸⁻³⁰²

Only limited comparisons between PIRRT and the other modalities of therapy are available and have demonstrated similar hemodynamic stability and metabolic control³⁰³⁻³⁰⁵ and comparable clinical outcomes.³⁰⁶ Peritoneal dialysis (PD) has long been used as a dialytic therapy in AKI, although its use has declined as the use of CRRT has increased. There are only a limited number of studies that have compared outcomes with PD to outcomes with other modalities of renal support in AKI.³⁰⁷⁻³¹⁰ Although one study demonstrated poorer survival with PD than with continuous hemofiltration,³⁰⁷ others have demonstrated biochemical and patient outcomes with high-volume peritoneal dialysis that are comparable to those seen with intermittent hemodialysis.³⁰⁸⁻³¹⁰

In the absence of data suggesting better survival or recovery of kidney function with any one modality of RRT, these modalities should be considered to be complementary.³ In general, the slower continuous (CRRT) and prolonged intermittent (PIRRT) modalities may be more optimal therapies for patients who are hemodynamically unstable. The

Box 55.6 Indications for Initiation of Renal Replacement Therapy in Acute Kidney Injury

Conventional Indications

- Volume overload unresponsive to diuretic therapy
- Electrolyte and acid-base disturbances refractory to medical management
 - Hyperkalemia
 - Metabolic acidosis
 - Severe hyponatremia
 - Severe hyperphosphatemia
- Overt uremic symptoms
 - Encephalopathy
 - Pericarditis

Relative Indications

- Progressive azotemia
- Persistent oliguria

choice of modality, however, should also reflect the local availability and expertise of the practitioners prescribing RRT and the nursing staff delivering the therapy.

TIMING OF INITIATION OF RENAL REPLACEMENT THERAPY

Standard indications for initiation of renal replacement therapy include volume overload unresponsive to diuretic therapy; electrolyte and acid-base disturbances refractory to medical management, particularly severe hyperkalemia and metabolic acidosis; and overt uremia, characterized pericarditis or encephalopathy (Box 55.6). Common practice, however, is to initiate RRT preemptively, well before the development of these advanced complications, in patients with severe AKI in whom imminent recovery of kidney function is unlikely. Uncertainty in predicting if and when kidney function will recover creates a clinical conundrum: the earlier the initiation of therapy, the greater the probability of dialyzing patients who, if managed conservatively, might have recovered kidney function and survived without needing RRT.

The clinical data guiding current practice regarding the optimal timing of initiation of RRT is weak, derived primarily from retrospective and observational cohort studies and small, underpowered prospective trials. Several observational studies published in the 1960s and early 1970s concluded that mortality rates were higher when dialysis was initiated late, when the BUN was above 160 to 200 mg/dL, as compared to earlier initiation, when the BUN was approximately 90 to 150 mg/dL.³¹¹⁻³¹³ Two subsequent small prospective studies compared more intensive and earlier initiation of therapy to more “conventional” management.^{314,315} In the first, a study of 18 patients with posttraumatic AKI, 5 of 8 patients (64%) assigned to the more intensive regimen which maintained the predialysis BUN below 70 mg/dL and serum creatinine below 5 mg/dL survived, as compared to 2 of 10 patients (20%) assigned to the less intensive strategy in which dialysis was not performed until the BUN approached 150 mg/dL, the creatinine reached 10 mg/dL, or other indications for dialysis were

present ($p = 0.14$).³¹⁴ In the subsequent study, 34 patients with severe AKI were assigned to either an intensive regimen, designed to maintain the predialysis BUN less than 60 mg/dL and serum creatinine less than 5 mg/dL or to a delayed and less intensive regimen, in which the BUN was allowed to reach 100 mg/dL and the serum creatinine 9 mg/dL when their serum creatinine reached 8 mg/dL.³¹⁵ Initiation of dialysis was 2 days earlier in the more intensive regimen. The mortality rate was slightly higher (59% vs. 47%) with the earlier and more intensive strategy; however, this difference did not reach statistical significance. On the basis of these data, the conventional approach to management of RRT in AKI has been to initiate therapy prophylactically, in the absence of specific metabolic indications or symptoms, when the BUN rises to approximately 80 to 100 mg/dL.

A number of more recent retrospective and observational studies have suggested that even earlier initiation of RRT may be associated with better survival.³¹⁶⁻³²⁸ For example, in a retrospective analysis of timing of initiation of CRRT in 100 consecutive patients with posttraumatic AKI, 39% of patients who were started on CRRT when their BUN was less than 60 mg/dL survived as compared to 20% of patients in whom CRRT was not begun until their BUN was more than 60 mg/dL.³¹⁶ Only one small randomized trial has attempted to rigorously evaluate the timing of initiation of therapy. In this study of 106 critically ill patients with AKI randomized to early high-volume, early low-volume, and late low-volume continuous venovenous hemodiafiltration (CVVHDF), there was no difference in survival between early and late initiation of therapy.³²⁹ A recent systematic review and meta-analysis of studies comparing early and late initiation of renal support published between 1985 and 2010, which included 15 unique studies, found an odds ratio for 28-day mortality rate of 0.45 associated with early initiation of renal support but noted that the methodologic quality of the included studies was low.³³⁰ However, there is an important methodologic flaw underlying the majority of studies that have evaluated the timing of RRT. In restricting their analyses to patients who actually received RRT, either “early” or “late,” these studies excluded the large number of patients who did not receive “early” RRT and either recovered kidney function and survived or died prior to reaching the criteria for “late” initiation of RRT.

The issue of severity of volume overload as an indication for initiation of renal support has garnered considerable attention and deserves special mention. The severity of volume overload at initiation of RRT is a strong predictor of fatality.^{263,331-333} For example, in a cohort of pediatric patients, there was an increase in mortality rate from 29% in patients whose fluid gain was less than 10% of premonitory body weight at the time of initiation of CRRT as opposed to 66% in patients with 20% or greater fluid overload at initiation of therapy and an adjusted odds ratio of death of 8.5 associated with 20% or greater fluid overload.³³³ Similarly, in a cohort of 396 critically ill adult patients, the presence of greater than 10% fluid overload at initiation of RRT was associated with an odds ratio of death of 2.1.²⁶³ Although these data provide a strong caution regarding overly aggressive volume administration in patients with AKI, the hypothesis that earlier initiation of renal support to prevent or reverse volume overload still needs to be tested in prospective clinical trials.

INTENSITY OF RENAL SUPPORT IN ACUTE KIDNEY INJURY

Assessment of the dose of both IHD and PIRRT is dependent on both the intensity of therapy delivered with each individual treatment, usually quantified in terms of urea reduction ratio or the fractional clearance of urea (Kt/V_{urea}), and the frequency with which the treatments are provided. For the continuous therapies, dose is usually expressed in terms of the total effluent flow (dialysate plus ultrafiltrate) normalized to body weight. Several small clinical trials suggested that an augmented dose of RRT, either as intermittent hemodialysis or CRRT, improves survival.³³⁴⁻³³⁶ These results were not consistent, however, across all studies^{329,337} and were not confirmed in two large multicenter randomized controlled trials.^{125,338} The Veterans Administration/National Institutes of Health (VA/NIH) Acute Renal Failure Trial Network (ATN) study randomized 1124 critically ill patients to lower- or higher-intensity RRT using a strategy that allowed patients to shift between modalities as hemodynamic status changed over time.¹²⁵ In the intensive arm, continuous venovenous hemodiafiltration (CVVHDF) was provided with a total effluent flow of 35 mL/kg/hour and conventional and prolonged intermittent hemodialysis were provided six times per week (daily, except Sunday); in the less intensive arm, the dose of CVVHDF was 20 mL/kg/hour and conventional and prolonged intermittent hemodialysis was provided three times per week (every other day, except Sunday). In the more intensive arm, 60-day all-cause mortality rate was 54% as compared to 52% in the less intensive arm. The Randomized Evaluation of Normal Versus Augmented Level (RENAL) Replacement Therapy study randomized 1508 patients in 35 ICUs in Australia and New Zealand to two doses of CVVHDF (25 or 40 mL/kg/hour) during their ICU stay. The survival rate to 90 days was 55.3% in both treatment arms.

The results of these two studies do not support the concept that more intensive renal support results in improved outcomes. It is recommended that intermittent hemodialysis be provided to deliver a total weekly therapy equivalent to that used in the ATN study (a target Kt/V_{urea} of 1.2-1.4 per treatment delivered three times per week).³ More frequent IHD may be necessary, however, for fluid management in extremely hypercatabolic patients and for control of severe hyperkalemia. For patients treated with CRRT, the recommended delivered dose of therapy is an effluent flow rate of 20 to 25 mL/kg/hour.³ Achieving this target dose may require the prescription of a slightly higher dose (25 to 30 mL/kg/hour) and careful attention to minimization of interruptions of therapy.

PROGNOSIS AND OUTCOMES

The mortality rate associated with AKI is high, although there is significant variation based on underlying cause, with much higher mortality rates associated with intrinsic forms of AKI than with prerenal or postrenal disease. In intrinsic AKI short-term mortality rates are approximately 50% and have changed little over the past 3 decades.* It is speculated

*See references 17, 21, 22, 24, 334, 339-350.

that this lack of improvement despite significant advances in supportive care most likely reflects a decrease in the proportion of patients presenting with isolated AKI, and a corresponding increase in the percentage of patients with AKI accompanied by multiple-organ dysfunction.^{22,24,351,352} In patients with sepsis-associated AKI, mortality rates are as high as 60% to 90%.^{17,61,341,351}

Multiple factors are associated with mortality risk in AKI and include male gender, advanced age, oliguria (<400 mL/day), a rise in the serum creatinine value of greater than 3 mg/dL, and coexistent sepsis or nonrenal organ failure. In general, these factors reflect severity of renal injury and overall severity of illness. However, even less severe AKI is associated with an increase in mortality risk. In a study of patients undergoing cardiothoracic surgery, increases in serum creatinine less than 0.6 mg/dL were independently associated with a nearly twofold increase in the 30-day mortality rate.³⁵³ Similarly, small increments in serum creatinine following radiocontrast agent administration, even if transient, are associated with increased rates of short- and long-term mortality.^{187,253,354,355} It remains unclear, however, whether such transient increases in serum creatinine actually mediate the adverse long-term outcomes or merely represent a biochemical marker of risk.³⁵⁶

In addition to the very high short-term mortality rate associated with AKI, there is also an increased risk of longer-term morbidity and mortality. It was previously believed that if a patient with AKI survived the acute episode the prognosis was good, with approximately 90% of patients having complete recovery of kidney function, 5% remaining dialysis dependent, and an additional 5% developing progressive deterioration in kidney function after initially recovering function. More recent data suggested a less optimistic prognosis. In recent clinical trials of RRT in AKI, rates of recovery have been highly variable.^{125,338,357} In the RENAL study, fewer than 10% of patients remained dialysis dependent as compared to 25% of surviving patients in the ATN study and 40% of patients in the Hanover Dialysis Outcomes study. The reason for this variability in recovery of kidney function across studies is unclear and may reflect differences in patterns of care or may reflect differences in the study population.

Approximately half of patients who recover renal function can be demonstrated to have subclinical kidney disease including modest decrements in GFR, defects in tubular function and urinary concentration, and tubulointerstitial scarring on kidney biopsy.³⁵⁸⁻³⁶¹ More importantly, patients who recover from AKI are at increased risk of progressive CKD and are at increased risk for the development of end-stage renal disease (ESRD).^{31,362-365} For example, in a 5% representative sample of elderly Medicare beneficiaries AKI in the absence of underlying CKD was independently associated with a 13-fold hazard for the development of ESRD within 2 years while AKI that developed in the setting of preexistent CKD was associated with a greater than 41-fold hazard for the development of ESRD.³⁶² Similarly, in a population-based cohort study using data from Ontario, Canada, 3769 patients who developed AKI that required temporary dialysis had a more than threefold increased risk for the development of ESRD over 3 years as compared to 13,598 matched control subjects who were hospitalized but did not develop AKI.³⁶³ In a similar analysis using data from

562,799 patients hospitalized in the Kaiser-Permanente of Northern California health system, AKI requiring transient dialysis was associated with a twofold increased risk of death over 6 years of follow-up and a 28-fold increased risk of developing progressive CKD.³¹ Mild AKI has also been associated with an increased risk of AKI. For example, increases in serum creatinine of as little as 0.3 to 0.5 mg/dL following an acute MI were independently associated with a greater than twofold increased hazard for ESRD and an approximately 25% increased hazard for long-term mortality.³⁶⁴

AKI is associated with prolongation of the length of hospitalization and substantial health resource utilization.^{284,345,366-368} In 1999, the cost of treating an episode of AKI was estimated to be \$50,000 per Quality Adjusted Life Year (QALY).³⁶⁹ In a more recent analysis, quality adjusted survival was poor among 153 ICU survivors who had recovered from AKI as compared to an age- and gender-matched community population.³⁷⁰ Although quality adjusted survival in this cohort was poor (15 quality adjusted years per 100 patient-years in the first year following discharge), the survivors' self-perceived health satisfaction was not significantly different from that of the general population.³⁷⁰ Similar poor health-related quality of life was also observed in a follow-up of 415 subjects who participated in the ATN study and survived at least 60 days, with 27% of respondents' health status corresponding to levels considered by the general population to be equivalent to or worse than death.³⁷¹

KEY POINTS

- Acute kidney injury is a common complication in critically ill patients and is accompanied by high rates of morbidity and mortality.
- The diagnosis of acute kidney injury is based on increases in the serum creatinine concentration or persistent oliguria despite adequate volume resuscitation.
- Multiple different pathogenic mechanisms can result in the development of acute kidney injury, including functional, hemodynamically mediated (prerenal) acute kidney injury, urinary tract obstruction (postrenal) acute kidney injury, and intrinsic acute kidney injury.
- Acute tubular necrosis, developing as the result of ischemia-reperfusion injury, nephrotoxic exposure, or sepsis, is the most common form of intrinsic acute kidney injury.
- The primary clinical manifestations of acute kidney injury include retention of nitrogenous waste products and disordered volume, electrolyte, and acid-base homeostasis.
- The initial assessment and management of the patient with acute kidney injury should focus on the identification and treatment of reversible etiologies including volume depletion, organ hypoperfusion, and urinary tract obstruction.

Continued on following page

KEY POINTS (Continued)

- Efforts to prevent AKI should be directed at maintaining renal perfusion and avoiding hypotension, selecting and dosing medications to minimize the risk of nephrotoxicity, and preventing nosocomial infections.
- Treatment of acute kidney injury is supportive, including optimizing volume status, treating electrolyte and acid-base disturbances, providing adequate nutrition, and dose adjusting renally excreted medications to prevent drug toxicity.
- In patients with severe AKI, renal replacement therapy should be employed to maintain volume status, correct electrolyte and acid-base disturbances, and remove the metabolic waste products responsible for the development of uremia.
- The majority of patients surviving an episode of acute kidney injury will recover kidney function; however, survivors are at increased risk for the development of chronic kidney disease and need for long-term dialysis.

SUMMARY

INTRODUCTION

Chronic kidney disease (CKD) is a common diagnosis in adult medicine.¹⁻⁶ In order to properly identify patients at risk for adverse outcomes and disease progression, extensive work has focused on early and appropriate classification over the last 10 years. In particular, the National Kidney Foundation (NKF) proposed a classification system for CKD in 2002 using estimated glomerular filtration rate (eGFR) as a method to categorize patients.^{7,8} Table 56.1 describes current NKF guidelines of CKD. In regard to critical care, CKD patients have higher mortality rate following critical illnesses.⁹ Understanding this population's physiology and underlying disease state may aid caregivers in attempting to improve this outcome.

This chapter will aim to define CKD and discuss the physiology of CKD in terms of blood pressure (BP), electrolytes, bone structure, and anemia. An emphasis will be given to the intensive care unit (ICU) management of these problems. When available, evidence-based guidelines will be reviewed and discussed. Unfortunately, the ICU management of CKD patients often is not guided by evidence-based therapy. As a result, guidelines developed from other populations will be reviewed with appropriate scrutiny.

DEFINITION AND ETIOLOGY

As previously stated, currently CKD is staged in a five-tier system based on eGFR (see Table 56.1). The diagnosis relies on abnormal kidney function or urinalysis findings for 3 months or more. The serum creatinine as well as age, sex, gender, and race is used to generate an eGFR from a quadratic equation derived from the Modification of Diet in Renal Disease Study.⁷ Most CKD patients do not progress to end-stage renal disease (ESRD), however, because of the very high cardiovascular and noncardiovascular mortality rate associated with this at-risk population.¹⁰⁻¹³ Proposals

exist to more clearly define elderly subjects with CKD stage 3 disease at risk for disease progression, though this practice has not become standard.¹⁴⁻¹⁶

Causes for CKD are broad and often multifactorial. Frequently, however, diabetes mellitus and hypertension play a major role. Hypertension may lead to kidney damage in the form of nephrosclerosis or chronic renal ischemia due to atherosclerotic vascular disease. An important recent development is the recognition that the higher prevalence of nondiabetic kidney disease in the African-American population may be due to genetic risk conferred by inherited variants in the apolipoprotein L1 gene (*APOLI*).¹⁷ Additional causes include immune-mediated glomerular diseases such as systemic lupus erythematosus, IgA nephropathy, membranous nephropathy, and other often pre-existing glomerulonephritides. Glomerulonephritis may be active as evidenced by hematuria and proteinuria or may have occurred in the patient's past, leading to abnormal kidney function but a relatively bland urinalysis. Alternatively, primary tubulointerstitial diseases could exist owing to reflux nephropathy, sarcoidosis, chronic infections, allergic reactions, or side effects from medications such as cyclophosphamide (Cytoxan) and lithium. In general, the diagnosis of CKD should warrant a higher index of suspicion for concurrent, and potentially undiagnosed, cardiovascular disease (CVD).

The CKD population is at risk for deterioration in kidney function during a hospitalization stay, particularly if a critical illness is present. Potential causative factors for this are listed in Box 56.1. Importantly, acute tubular necrosis may occur without obvious hypotension, and patients with reduced kidney function are more at risk for this complication.¹⁸

DIAGNOSIS

Intrinsic to the eGFR formula, as well as other estimates of renal function from the serum creatinine, is the

Table 56.1 Chronic Kidney Disease Stages

Stage	eGFR (mL/min/ 1.73 m ²)	Urinalysis Findings
1	≥90	Hematuria, proteinuria, or imaging abnormalities at >3 months
2	60-89	Hematuria, proteinuria, or imaging abnormalities at >3 months
3	30-59	↑ or normal
4	15-29	↑ or normal
5	0-14	↑ or normal

Box 56.1 Factors Leading to Deterioration in Renal Function During Hospitalization in Patients with Chronic Kidney Disease

Volume depletion: prerenal, including “normotensive” sepsis, renal vasoconstriction due to medications or hypercalcemia
 Obstruction
 Renal vascular disease: atherosclerotic with volume depletion, thrombotic, or embolic disease
 Upper urinary tract infection: bilateral or unilateral with single kidney including a kidney transplant
 Nephrotoxic medications: allergic inflammation, tubular injury
 Glomerular disease: IgA or postinfectious related to infection

IgA, immunoglobulin A.

presumption that a patient’s serum creatinine is stable. This finding may not be the case in ICU patients; as a result, imprecision should be expected in kidney function estimation in ICU patients.¹⁹ Serum creatinine is now recognized to potentially underestimate the level of renal function in a large population of patients, particularly those with low weight, small muscle mass, and liver disease.²⁰ Additionally, both endogenous and exogenous factors can influence the measurement of serum creatinine.²¹⁻²⁴ Box 56.2 describes situations in which serum creatinine measurements may not adequately reflect kidney function. Importantly, some vasoactive substances can impart a negative interference on creatinine values if the creatinine sample is obtained from a central line used for vasopressors.²⁵ Nonetheless, creatinine variation has improved since values have been standardized to reference values.^{26,27}

In general, current guidelines recognize the importance of stage 3 through 5 kidney disease for prognostication in outpatient and inpatient outcomes. Proteinuria is now associated with increased cardiovascular risk at all glomerular filtration rates (GFRs), including normal GFRs.²⁸ Even mild kidney dysfunction, defined typically as a serum creatinine level over 1.5 mg/dL or GFR below 60 mL/minute, is

associated with worse outcomes after coronary artery bypass graft (CABG), cardiac valvular, and general surgery.²⁹⁻³³

Concern exists about the accuracy of the Modification of Diet in Renal Disease (MDRD) equation at higher GFRs. For example, the newer creatinine-based CKD-EPI formula equation leads to a lower prevalence rate of CKD stage 3 than the MDRD equation, as more patients have an eGFR above 60 mL/minute.³⁴⁻³⁶ Measurement of serum cystatin C levels, a protein produced by all nucleated cells and freely filtered by the glomerulus, may provide more accurate estimates of kidney function than creatinine-based equations, particularly when kidney function is close to normal.³⁷ Cystatin C may also provide prognostic information about future cardiovascular events.¹² In fact, cystatin C has been proposed as a marker of “preclinical” kidney disease based on worse cardiovascular outcomes in elderly subjects with higher cystatin C levels.³⁸ Despite a growing body of literature, use of cystatin C is not routine in clinical practice.

When serum creatinine is stable and the eGFR formula is felt to inaccurately measure kidney function, creatinine clearance can be measured by using a 24-hour urine collection through the following formula:

$$\text{Creatinine clearance (dL/24 hours)} = \frac{(\text{Urine creatinine (mg/dL)} \times (\text{volume of urine (dL)}) / \text{Plasma creatinine (mg/dL)})}{24}$$

In this equation, units will need to be converted from dL/24 hours to mL/minute by a conversion factor of 0.0694.

If this measure is pursued, clinicians are counseled to pay close attention to units as well as the expectation that men excrete 1500 to 2500 mg/day of creatinine and women excrete 1000 to 1500 mg/day of creatinine.³⁹ If a lower amount of urinary creatinine is obtained, the possibility of an undercollection should be considered. It is also worthwhile to note that historically, drug dosing has been determined by creatinine clearance and not eGFR.

In summary, estimating kidney function in ICU patients may be challenging because of the absence of steady-state conditions and irregularities in body size and fluid compartments. Critical care providers need to understand the strengths and weaknesses of measuring kidney function in these patients.

PHYSIOLOGY

HYPERTENSION

Over 80% of CKD patients with eGFR less than 60 mL/minute have hypertension.⁵ This has several important impacts on the management of ICU patients. First, longstanding hypertension, if uncontrolled, leads to adaptations in autoregulation. Autoregulation refers to the ability of blood vessels to constrict and dilate in the presence of hypertension and hypotension, respectively. Consequently, patients become acclimated to BPs near their “typical” BP and may not tolerate lower BPs despite these apparent lower values appearing in the normal range. A consequence of this may be hypoperfusion to the kidneys as well as the brain, heart, intestine, and other critical organs at BP levels that appear normal. If a history of poorly controlled hypertension is obtained, an astute clinician should aim to keep BP close to the level the patient being treated is used to. This very much requires individualized attention and thorough history taking.

Second, CKD leads to sodium retention.^{40,41} The most notable ICU impact this will have is the potential for volume retention and the need for diuretics to manage hypertension in the CKD population.⁴²⁻⁴⁴ Several mechanisms lead to the development of hypertension in the CKD population. They include upregulation of the renin-angiotensin system, increased sympathetic nervous system activity, and impairment of endothelial-dependent arterial smooth muscle relaxation.⁴⁵⁻⁵¹ Owing to the preceding mechanisms, CKD patients may develop more edema and volume overload with equivalent amounts of intravenous (IV) fluids. One worthwhile consideration, however, is that sodium retention associated with CKD may be counterbalanced by sodium loss from excessively high BP levels. This phenomenon, known as pressure natriuresis, may explain the rapid drops observed in BP in hypertension emergencies once excess sympathetic activity is controlled.

ELECTROLYTE DISORDERS

SODIUM

Sodium homeostasis in patients with CKD is abnormal. With increased loss of sodium in the urine, but declining numbers of functioning nephrons, sodium balance is maintained.⁵² Though CKD patients are sodium “avid” and tend toward states of volume overload, they are less able to increase sodium retention in times of need and subsequently are also at risk for volume depletion. In comparison, subjects with normal renal function can quickly increase sodium absorption and avoid volume-depleted states.⁵³ Tubulointerstitial disease and obstructive uropathy may be particularly at risk for episodes of volume depletion due to their recognized inability to increase sodium reabsorption in times of volume depletion.⁵⁴

Patients with CKD thus are a group at risk for both volume depletion as well as volume overload. ICU illnesses may confound this because of irregularities in physical examination findings in this population. Specifically, elevated BP and edema in the CKD population are frequently present but do not represent states of intravascular volume overload. In summary, close attention to assessment of volume

status and need for supplemental fluids or diuresis is warranted in the CKD population.

When volume overload is present, iatrogenic sources may be playing a role. Potential sources of sodium include maintenance IV fluids (including bicarbonate), antibiotics, and nutritional sources including total parenteral nutrition (TPN). Tracking fluid intake and output (“Is and Os”) does not clearly differentiate between the electrolyte makeup of the various sources. Consequently, volume overload may develop insidiously. When volume overload develops, the standard approach involves minimizing sodium-containing sources and initiating a diuretic regimen. Diuretics range from the more gentle thiazide diuretics, which are ineffective with a GFR below 30 mL/minute, to more potent loop diuretics. In general, if significant volume removal is desired, a diuretic regimen twice a day (every 12 hours) should be prescribed to avoid excess sodium reabsorption in the period after the major diuretic effect.⁵⁵ Chronic administration of diuretics, prior to ICU admission, may lead to adaptive processes necessitating higher diuretic doses, combination therapy, or alternative approaches to volume overload states.⁵⁶⁻⁵⁹ Furosemide is the loop diuretic that may be closest to lasting 24 hours.⁶⁰ Doses of loop diuretics need to be increased as renal function declines. Significant variability in loop diuretic kinetics exist; if a dose does not yield an increase in urine output within 2 hours, consideration should be given to increasing the dose. Alternatively, continuous infusion of loop diuretics may provide a better diuresis with less toxicity.^{61,62} Typically infusion rates of furosemide are 10 to 40 mg/hour. When a loop diuretic drip is ordered, a bolus should be given prior to initiating therapy to avoid a significant delay in efficacy.

Diuretic failure is common in the CKD population. Potential explanations in an ICU population include acute kidney injury, inadequate dosing, and distal tubular hypertrophy due to chronic diuretic use. When high-dose loop diuretics do not achieve adequate diuresis, the addition of metolazone may improve urine output. Historically, metolazone is given 30 minutes prior to the loop diuretics, though it may be efficacious if given at other times as well. Finally, isolated ultrafiltration or potentially dialysis may be required for volume removal. Significant attention has been given to the importance of elevated intra-abdominal pressures leading to a reduction in renal function and, potentially, ability to respond to diuretics.⁶³⁻⁶⁸

WATER

Water concentration and dilution are abnormal in CKD patients. Normal patients can dilute and concentrate urine within a range of 40 to 1400 mOsm/kg.⁶⁹ CKD leads to a narrower range of urine osmolality. Specifically, patients with advanced CKD have a urine osmolality much closer to 300 mOsm/kg; the ability to adjust urine osmolality declines as urine function worsens.⁷⁰ Consequently, patients with CKD are prone both to hypernatremia and hyponatremia. Loop diuretics may further worsen the kidney's ability to concentrate and dilute urine.⁷¹

The approach to hypernatremia and hyponatremia is similar to that in other patients. In hypernatremia cases, concurrent illnesses often lead to patients being unable to obtain water for themselves; a high urine output due to hyperglycemia or a high urea concentration may worsen

this. Elevated urea, as with high serum glucose levels, functions as an osmolar agent in the tubular lumen and creates a state of relative antidiuretic hormone (ADH) resistance with the potential for substantial free water loss.⁷²

Hypernatremia can lead to significant agitation and should be treated aggressively with increased water either intravenously, in the form of hypotonic IV fluids, or enterally. When severe, an estimation of free water deficit is appropriate. Unexplained polyuria with a low urine osmolality, hypernatremia, and CKD in an ICU patient with unclear history should warrant an investigation for previous lithium use.⁷³

Hyponatremia reflects irregularities in water excretion in the vast majority of cases. CKD patients are less able to excrete water owing to the inability to lower urine osmolality.⁷⁴ Sources of water include IV fluids, medications mixed in dextrose, and enteral sources. Patients often are not aware or not forthcoming in the amount of water they drink, though this is less an issue in ICU patients. The approach for most CKD patients is similar to that in other cases of hyponatremia, which involve looking for and reducing causes of increased water intake. Importantly, sodium abnormalities in the CKD patient, both with and without congestive heart failure, are associated with a higher mortality rate.⁷⁵

POTASSIUM

Potassium (K^+) regulation is an essential function of the kidneys in normal states. CKD patients routinely maintain serum K^+ in the normal range despite losing up to 90% of renal function.^{76,77} Mechanisms underlying the maintenance of normal serum K^+ in advanced CKD include increased K^+ excretion per functioning nephron, increased gastrointestinal (GI) elimination of K^+ , and increased uptake of K^+ by cells.⁷⁸ Diabetes mellitus, however, may exacerbate the development of hyperkalemia due to the presence of a distal tubular acidosis (type 4) from aldosterone resistance. Hyperkalemia may also be present due to current diuretic use or renovascular hypertension.⁷⁹ Its presence is associated with a higher risk of death and future ESRD needs in the CKD population.⁸⁰

ICU patients with CKD represent a population prone to irregularities in K^+ homeostasis, in particular, hyperkalemia.^{81,82} Potential causes of hyperkalemia include insulin deficiency, hypoaldosteronism, and a loss of normal intestinal function, which plays a role in increased potassium excretion in CKD patients. Decreased blood flow to muscle and intestines in times of critical illness may impede potassium cellular uptake and excretion, respectively. Tissue ischemia from trauma, hypoxia, or tumor lysis is associated with an elevation in K^+ which may occur quickly.⁸³ One additional clinical consideration is that CKD patients who are fasting may develop surprising levels of hyperkalemia without any apparent cause due to low levels of insulin.⁸⁴ Glucose-containing IV fluids may avoid this.

The evaluation of hyperkalemia in CKD patients begins with assessing the cause. Typically, this includes close scrutiny of medications, IV fluids, and types of nutritional support. Frequently, ICU patients receive nutrition very different from what the body is used to and cannot manage a higher load of K^+ , especially in states of relative tissue perfusion. Importantly, many CKD patients are on diuretics as

Box 56.3 Causes of Hyperkalemia, with Associated Mechanisms, in Patients with Chronic Kidney Disease in the Intensive Care Unit (ICU) Setting

Medications

Trimethoprim—↓ renal K^+ excretion^{135,136}
 NSAIDs, ACE inhibitors, ARBs—↓ renal K^+ excretion
 Heparin—↓ aldosterone synthesis¹³⁷
 Beta blockers, nonselective—↓ cellular K^+ uptake¹³⁸
 Triamterene, spironolactone, amiloride—↓ renal K^+ excretion
 Digoxin overdose—↓ cellular K^+ uptake¹³⁹
 Succinylcholine use with trauma/critical illness—↑ K^+ release from cells¹⁴⁰
 Pencillin G—↑ K^+ load^{141,142}

Clinical Conditions

Renal tubular acidosis (associated with diabetes)—↓ renal K^+ excretion

part of their routine outpatient medications; simply stopping these medications may lead to states of hyperkalemia. Hyperosmolality leads to a K^+ shift out of cells caused by solvent drag; in its most common presentation, hyperglycemia, this can be reversed quickly with the use of insulin. Metabolic acidosis may be associated with hyperkalemia though organic acidosis states appear to cause less hyperkalemia than nonorganic acid-induced states.⁸⁵

Medications are an important and growing cause of hyperkalemia. Congestive heart failure and proteinuric renal disease remain as two indications for possible dual renin-angiotensin-aldosterone blockade; hyperkalemia has been observed more frequently since the publication of the RALES trial.⁸⁶ Box 56.3 lists some common causes of hyperkalemia in the CKD population and the associated mechanisms.⁸⁷ The presence of hyperkalemia should warrant close attention to affected patients as its presence is associated with increased mortality rate.⁸⁸

METABOLIC ACIDOSIS

The kidneys and lungs regulate acid excretion by the body. Kidney excretion of acid occurs through two mechanisms: as protons bound to anions such as phosphate and through ammoniogenesis. As kidney function declines below a GFR of 30 mL/minute, the excess excretion of protons by each remaining functional nephron is no longer able to keep serum bicarbonate in the normal range. As a result, bicarbonate levels in CKD patients frequently range in the 18 to 22 mmol/L range due to a modest increase in the serum anion gap.⁸⁹ A recent trial showed sodium bicarbonate, supplemented orally, could delay kidney disease progression (Fig. 56.1).⁹⁰

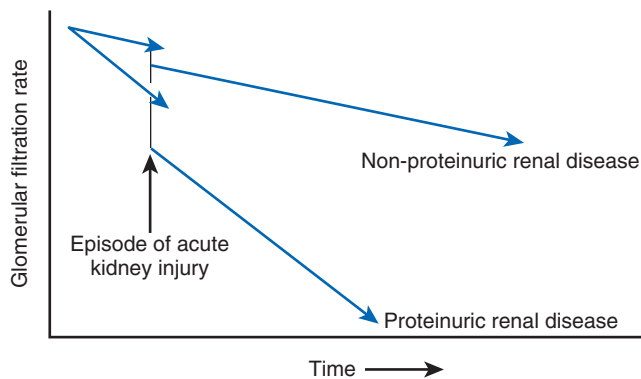

Figure 56.1 Rate of decline in renal function over time showing higher rate of decline in patients with proteinuric renal disease and potential for episodes of acute kidney injury to hasten kidney disease progression.

In ICU CKD patients, serum bicarbonate and anion gaps are often further worsened by concurrent conditions including lactic acidosis, ketoacidosis, or dilution due to aggressive volume resuscitation. The latter case, dilutional acidosis, will present with a worsening serum bicarbonate in the days following admission to the ICU and institution of IV fluids; the anion gap should not change significantly. In general, an anion gap over 20 should warrant a workup for other causes of increased acid generation. Medications may also worsen acidosis in the CKD population owing to disturbances in ammonia production as well as excess acid production in the form of lactic acid, keto acids, and pyroglutamic acids.^{91,92}

MINERAL BONE DISORDER

Substantial information has developed in the last several years about the mechanisms leading to abnormal calcium and bone metabolism in patients with CKD. Historically, this disorder was named “renal osteodystrophy.” The current preferred term is CKD mineral bone disorder.⁹³ The main developments reflects the growing importance of FGF-23 on phosphate and parathyroid regulation and the relaxation of guidelines for strict parathyroid hormone (PTH) control at least in the ESRD population.⁹⁴

FGF-23 is a phosphaturic protein produced by bone. Phosphaturia occurs as a result of decreased expression of NaPi-2a cotransporters in renal proximal tubular cells.⁹⁵ In addition, FGF-23 leads to a reduction in 1,25(OH)₂D production by the kidney.⁹⁶ Its concentration increases earlier in the course of CKD than PTH. These adaptations initially keep calcium and phosphorus levels well maintained despite progressively increased serum FGF-23 and PTH levels.

From an ICU patient perspective, hypocalcemia will routinely be encountered owing to the preceding developments. Hypocalcemia, in the absence of other causes, suggests renal disease is chronic. Serum phosphorus levels may similarly be elevated as GFR declines. Dietary phosphorus restriction and phosphorus binders are the primary treatments for this. There are limited prospective data evaluating the best management of CKD mineral bone disorder, and therapy is for the most part dictated by nonrandomized studies and consensus guidelines. Elevations of FGF-23 are associated with a higher risk of mortality across multiple

levels of kidney function.⁹⁷ Important issues for anyone caring for CKD patients with abnormalities of calcium bone deposition in the ICU include the following:

- Avoidance of phosphorus-containing GI stimulants because of risk of systemic absorption and acute kidney injury
- Recognition that hypocalcemia may be chronic: typically, patients become adapted to this with a normal ionized calcium due to concurrent metabolic acidosis. Rapidly raising pH may lower serum calcium levels acutely and predispose patients to arrhythmias.⁹⁸
- Consideration for other causes of hypocalcemia and hyperphosphatemia, in particular, cell death from rhabdomyolysis and tumor lysis syndrome

ANEMIA AND HEMATOLOGIC DISEASE

Erythropoietin is produced by the kidney and stimulates hematopoiesis in the bone marrow. CKD is associated with a reduction in erythropoietin levels and consequent anemia. As CKD progresses toward ESRD, anemia becomes more severe.⁹⁹ As a general rule, most ESRD patients receive supplemental erythropoietin to increase their hemoglobin (Hb) level and avoid transfusions.

Two large trials published in 2006 significantly altered the management of anemia of CKD.^{100,101} The CHOIR and CREATE trials both showed, in a well-designed format, that randomization to a normal Hb did not improve outcomes and increased some adverse events. As a result, goal Hb levels have dropped closer to 10.0 g/dL in general practice and the use of these medications has fallen substantially. These trials reinforced earlier data that showed that aiming for a normal Hb, achieved through supplemental erythropoietin, in the CKD population was dangerous.¹⁰² Similar results were noted with darbapoietin alpha.¹⁰³ These studies clearly show adverse events from supraphysiologic Hbs in CKD patients. The impact of relative reductions in Hb in critically ill CKD patients is not well studied.

In CKD with critical illnesses the problems of anemia are often magnified. How the anemia of CKD impacts hospital course is not well understood. The current preference of minimizing transfusions and keeping Hbs in a lower range, based on trials for the most part on non-CKD patients, has led to a reduction in Hb in CKD patients as well.¹⁰⁴⁻¹⁰⁶ It is important to consider that CKD patients may not be able to recover Hb after acute illness because of reduced erythropoietin production.

Acute drops in Hb in ICU CKD patients should be managed similar to those in non-CKD patients. Chronic anemia should not be presumed to be due to CKD, and routine evaluations should still occur, including stool studies and iron status assessment. CKD patients, when blood urea nitrogen (BUN) levels increase above 100 mg/dL, are more prone to bleeding because of irregularities in platelet functional activity.¹⁰⁷⁻¹⁰⁹ Dialysis may reduce the risk of bleeding due to azotemia and “uremic platelets,” though variable data on this point exist.¹¹⁰⁻¹¹² Additionally, desmopressin will stimulate von Willebrand factor release acutely though tachyphylaxis develops after the first dose.^{113,114} Finally, conjugated estrogens may provide a sustained reduction in bleeding complications in CKD patients who have recurrent

GI bleeding.¹¹⁵ Low-molecular-weight heparin clearance is reduced in patients with low GFRs. Appropriate dose reductions should occur; currently, no guidelines exist for dosing these medications with a GFR below 15 mL/minute, and their use in these settings should be avoided.

END-STAGE RENAL DISEASE

Patients with ESRD make up a large and growing percentage of the CKD population. In the United States, 90% of this population receives renal replacement therapy (RRT) in the form of in-center hemodialysis at the time of dialysis initiation.⁵ Efforts are under way to move more of this care to the patient's home in the form of home hemodialysis or peritoneal dialysis.

ESRD patients have a higher mortality rate when admitted to ICUs.^{116,117} Indications for admission may be dialysis specific such as access complications or volume overload or may be due to other comorbid illnesses. Most commonly, indications include cardiovascular causes including acute coronary syndromes and strokes, other infectious causes, and GI hemorrhages. Commonly used ICU prognostic scoring systems such as Apache II and III, Simplified Acute Physiology Score (SAPS) II, and Sequential Organ Failure provide reasonable prognostication of patients with ESRD.¹¹⁸

Attention to a dialysis patient's access for ESRD is essential in the care of any ICU ESRD patient. Arteriovenous fistulas (AVFs) and arteriovenous grafts (AVGs) may potentially occlude during hypotension.¹¹⁹ Loss of dialysis access due to complications from hypotension or potential iatrogenic causes such as restraints could pose a severe hardship for the patient upon recovery from the current illness.¹²⁰⁻¹²² A relatively recently recognized issue is the need to avoid brachial and subclavian access whenever possible in patient who may currently or imminently need an AVF or AVG. The reason is the frequent development of venous stenosis or thrombosis, which could hamper future access maturation; studies show a high prevalence of thrombosis, over 30%, following peripherally inserted central catheter (PICC) line placement.¹²³ Tunneled intrajugular catheters are an appropriate option in this population.¹²⁴ Subclavian lines, even temporarily, pose similar complication risks. Currently, the Kidney Disease Outcomes Quality Initiative (KDOQI), sponsored by the National Kidney Foundation, recommends not placing PICC lines in patients with CKD.¹²⁵

Common causes of infection in the ESRD population are cellulitis, pneumonia, bacteremia, and pyocystitis.¹²⁶ In the absence of a clear cause of infections, a high index of suspicion for access infection should be maintained for ESRD patients presenting with unexplained sepsis if a tunneled dialysis catheter is being used. Generally, catheters do not show signs of infection. Initially, antibiotic therapy should broadly cover gram-positive and gram-negative organisms as these are the most common organisms associated with infection.¹²⁷ Vancomycin and gentamicin, prescribed with a loading dose to achieve therapeutic targets based on local sensitivity data, are standard regimens. Considering the prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA), a cephalosporin-only regimen may significantly delay effective therapy.¹²⁸ An important consideration is the

peritoneal dialysis patient who still makes urine. If feasible, these patients should not receive aminoglycoside therapy in order to maintain their important residual renal function. Instead, a third-generation cephalosporin should be used. Whenever possible, old culture results should be used to guide initial treatment as antibiotic resistance is commonplace. When a tunnel infection is suspected in a hemodialysis patient, as evidenced by an erythematous track around the course of the catheter or purulent drainage from the tunnel itself, catheter removal should urgently occur. When an AVG is infected, urgent removal or resection should also occur. Old, occluded AVGs may represent a source for chronic indolent infections and inflammation.¹²⁹

Ideal fluid management in ESRD patients with sepsis requires close monitoring and repeat assessments. Limited data exist to guide the clinician, and in states of classic sepsis, appropriate volume resuscitation should occur. Nonetheless, thoughtful consideration as to when to moderate fluid repletion in the septic, intubated ESRD patient may improve subsequent ventilator weaning.

KIDNEY TRANSPLANT PATIENTS

Data from the 2008 USRDS survey show that patients with a functioning kidney transplant make up 30% of all ESRD patients.⁵ Infectious and cardiovascular complications are the most frequent complications requiring admission to an ICU.

The risk of infection in a kidney transplant patient is complex and related to a number of factors including the health of the allograft, specific donor and recipient factors (CMV status, for example), adequate prophylaxis, up-to-date and effective vaccination, and the level of immunosuppression.¹³⁰ In the early post-transplant period, generally defined as 1 month or less, typical postoperative complications, including *Clostridium difficile*-associated colitis, are most common. In months 1 to 6 following transplantation, opportunistic infections and viral infections are the predominant source of infection due to the residual effects of induction immunosuppression. After 6 months, typical community-acquired organisms remain the primary source of infection. Infection with cytomegalovirus is an important cause of morbidity in the transplant population and may be present outside the first 6 months. Specific guidelines exist regarding prophylaxis, screening, and treatment for CMV infection in the solid organ transplant patient.¹³¹

DRUG DOSING

Drug dosing in CKD patients requires close attention to current levels of kidney function and an understanding of the risks and benefits of the medication prescribed. Two points are worthy of specific attention. First, drug dosing has historically been defined by creatinine clearance and not eGFR.^{132,133} The second is that CKD patients, particularly with advanced disease, are a population that is understudied in terms of medication dosing.¹³⁴ Antibiotic dosing in the critically ill patient is an area in which the toxicity of over-dosage needs to be balanced against the possibility of

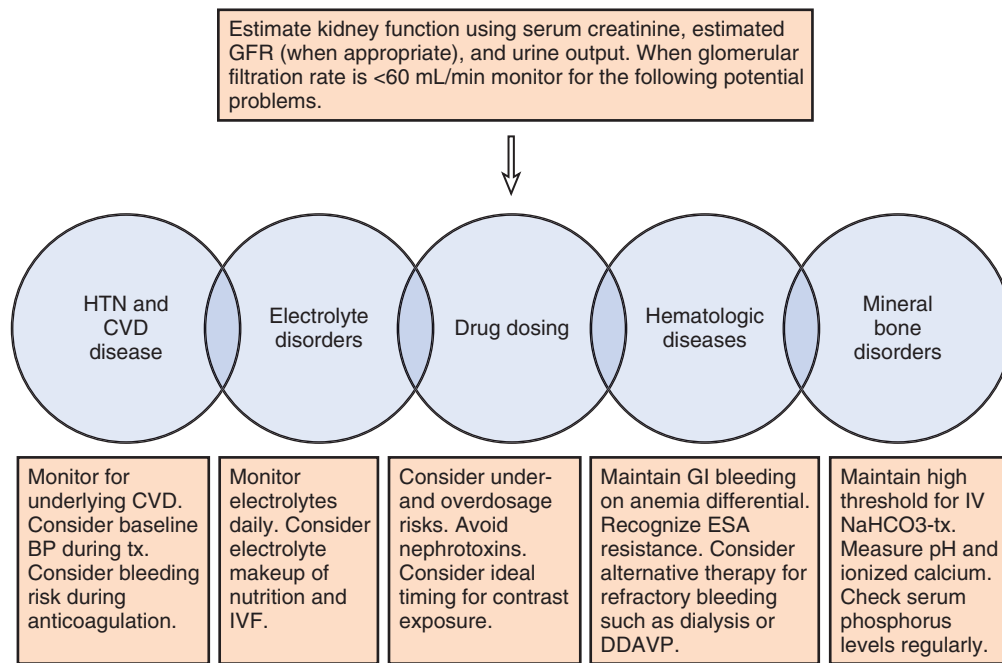

Figure 56.2 Select management principles for patients with chronic kidney disease.

subtherapeutic dosing. Recognizing that serum creatinine may not reflect true GFR is an important part of this process.

SUMMARY

The prevalence of CKD and ESRD in the ICU has increased and this population is prone to poor outcomes. Ideal care of this population includes the recognition that serum creatinine may not reflect GFR, patients are prone to volume overload and volume depletion, and abnormalities in Hb, pH, calcium, and phosphorus may reflect normal and not abnormal physiology. Drug dosing needs to be tailored to individuals, and risks of underdosage as well as overdosage must be considered. See [Figure 56-2](#) for a summary of management principles for CKD.

KEY POINTS

- CKD patients frequently die of CVD; a low index of suspicion for occult CVD should guide caregivers.
- Serum creatinine frequently does not accurately reflect current level of kidney function in the ICU patient.
- CKD is associated with sodium retention and a higher prevalence of hypertension. Acute BP control should take into account baseline BP control to avoid tissue underperfusion.
- Electrolyte disorders, in particular hyperkalemia, in the ICU CKD population, are frequent.
- Acute treatment of chronic metabolic acidosis may lead to iatrogenic falls in serum calcium.

KEY POINTS (Continued)

- Brachial and subclavian access is relatively contraindicated in the advanced CKD and ESRD population owing to their future impact on maturing vascular access for dialysis.
- Drug dosing in CKD patients is poorly studied. Clinicians should be cautious of under- and overdosage issues.

Acid-base, electrolyte, and metabolic disturbances are common in the intensive care unit (ICU). Indeed, critically ill patients often suffer from compound acid-base and electrolyte disorders. Successful evaluation and management of such patients requires recognition of common patterns (e.g., hypokalemia and metabolic alkalosis), and an ability to discern one disorder from another. This chapter is intended to provide intensivists with the tools they need for diagnosis and treatment of the acid-base, electrolyte, and metabolic disorders encountered in the care of critically ill patients. By reviewing the elements of normal physiology in these areas, and presenting a general diagnostic scheme for each condition, we hope to provide readers with a foundation for approaching not only common, but novel and complex disorders.

ACID-BASE HOMEOSTASIS

Normal acid-base balance depends on the cooperation of at least two vital organ systems: the lungs and the kidneys. The gastrointestinal (GI) tract also is involved in many acid-base disturbances. Multiorgan system involvement, therefore, provides the backdrop for the acid-base disorders commonly seen in critically ill patients.

NORMAL ACID-BASE PHYSIOLOGY

Normal biochemical and physiologic function requires that the extracellular pH be maintained within a very narrow range. Although the “normal” range of pH in clinical laboratories is 7.35 to 7.45 pH units, the actual pH in vivo varies considerably less.¹ This tight control is maintained by a complex homeostatic mechanism involving buffers and the elimination of volatile acid by respiration.

The principal extracellular buffer system is the carbonic acid/bicarbonate pair. The equilibrium relationships of the components of this system are illustrated as follows:¹

From these relationships, the Henderson-Hasselbalch equation is derived:

$$\text{pH} = \text{pK} + \log_{10} \frac{[\text{HCO}_3^-]}{\alpha_{\text{CO}_2} \cdot \text{PCO}_2}$$

In this equation, α_{CO_2} is the solubility coefficient of CO_2 (0.03), and pK is the equilibrium constant for this buffer pair (6.1). Rearrangement yields the Henderson equation:

$$[\text{H}^+] = 24 \cdot \frac{\text{PCO}_2}{[\text{HCO}_3^-]}$$

It is apparent from this equation that disturbances in the proton concentration of the extracellular fluid (ECF) (and blood) may be due to perturbation in the numerator, the denominator, or both. Disturbances that affect the P_{CO_2} primarily are called *respiratory* disturbances, and those that affect the HCO_3^- primarily are called *metabolic*.

Acid-base homeostasis depends on compensation for a primary disturbance. Compensation for a respiratory disturbance is metabolic, and compensation for a metabolic disturbance is respiratory. Furthermore, it is clear from the previous equations that in order to mitigate the change in proton concentration or pH, the direction of the compensation must be the same as the direction of the primary disturbance. Thus, consumption of bicarbonate will be accompanied by hyperventilation and a consequent reduction in P_{CO_2} . A simple acid-base disturbance is considered to consist of the primary disturbance *and* its normal compensation. A complex acid-base disturbance consists of more than one primary disturbance. In order to detect complex acid-base disturbances, one must be familiar with both the direction and magnitude of normal compensation (shown in Table 57.1).² More than one metabolic disturbance may coexist (e.g., metabolic acidosis and metabolic alkalosis), but only one respiratory disturbance is possible at a time.

In the present section, we will discuss disorders that affect the metabolic component of acid-base homeostasis: metabolic acidosis and metabolic alkalosis. Respiratory disturbances affecting acid-base balance will be discussed elsewhere (Chapters 37 and 40).

METABOLIC ACIDOSIS

DEFINITION AND CLASSIFICATION

A metabolic acidosis is a process that, if unopposed, would cause *acidemia* (a high hydrogen ion concentration, or low pH, of the blood) by reducing the extracellular bicarbonate concentration. The extracellular bicarbonate concentration may be reduced by either addition of acid and consequent consumption of bicarbonate, or by primary loss of bicarbonate.

An adult eating a normal diet generates 16,000 to 20,000 mmol of acid a day.³ Almost all of that acid is in the form of carbonic acid, resulting from CO_2 and water generation in the metabolism of carbohydrates and fats. Individuals with normal ventilatory capacity eliminate this prodigious acid load through the lungs, thus the term *volatile acid*. The remainder of the daily acid load, about 1 mmol/kg body

weight per day, derives from metabolism of phosphate- and sulfate-rich protein (yielding phosphoric and sulfuric acid). These nonvolatile or *fixed acids* are buffered, primarily by extracellular bicarbonate under normal circumstances. The kidneys are responsible for regenerating the consumed bicarbonate by secreting hydrogen ions (protons) in the distal nephron. These secreted protons must be buffered in the tubule lumen in order to allow elimination of the daily fixed acid load within the physiologic constraint of the minimum urinary pH. The urinary buffers are composed of the filtered sodium salts of the phosphoric acid and ammonia, which is synthesized in the proximal tubule and acidified in the collecting duct to form ammonium (NH_4^+). Under conditions of acid loading, the normal kidney reabsorbs all the filtered bicarbonate in the proximal tubule. Urinary net acid excretion therefore comprises phosphoric acid (so-called titratable acidity, because it is quantified by titrating the urine with alkali to pH 7.40) and ammonium, less any excreted bicarbonate.⁴

Many factors modify the kidney's capacity to regulate acid-base balance. For example, renal ammoniogenesis is stimulated by acidemia, and inhibited by alkalemia, and thus participates in a homeostatic feedback loop.¹ Hyperkalemia inhibits and hypokalemia stimulates renal ammoniogenesis. Hypokalemia further stimulates acid secretion by activating the Na^+H^+ exchanger in the proximal tubule and the H^+/K^+ -ATPase in the collecting duct. Finally, aldosterone stimulates both proton and K^+ secretion in the collecting duct. For these reasons, hypokalemia tends to perpetuate a metabolic alkalosis, and hyperkalemia a metabolic acidosis.¹

Metabolic acidosis can be caused by excessive production of fixed acid, decreased renal secretion of fixed acid, or loss of bicarbonate, either through the kidney or through the intestine.⁴ The net effect of any of these processes is a reduction in the blood bicarbonate concentration. The plasma *anion gap* helps to distinguish among the various causes of metabolic acidosis. Of course, because of charge neutrality, the sum of the concentration of all cations in the plasma is equal to the sum of all the anions. By convention, however, the anion gap is defined as the difference between the plasma sodium concentration and the sum of the bicarbonate and chloride concentrations. It represents the concentration of anions that are normally unmeasured by a basic metabolic chemistry panel.⁵ The anion gap normally is about 8 mmol/L, but it varies widely according to the methods employed by the clinical chemistry laboratory.⁶ The anion gap is composed mainly of albumin, along with phosphates, sulfates, and organic anions.

Table 57.1 Expected Compensation for Simple Acid-Base Disorders

Disorder	Primary Disturbance	Compensation	Magnitude	Time to Completion
Metabolic acidosis	↓ $[HCO_3^-]$	↓ P_{CO_2}	$1.5 \cdot [HCO_3^-] + 8$	12-24 hours
Metabolic alkalosis	↑ $[HCO_3^-]$	↑ P_{CO_2}	$0.9 \cdot [HCO_3^-] + 9$	12-24 hours
Respiratory acidosis, acute	↑ P_{CO_2}	↑ $[HCO_3^-]$	1 mmol/L/10 mm Hg	<6 hours
Respiratory acidosis, chronic	↑ P_{CO_2}	↑ $[HCO_3^-]$	3.5 mmol/L/10 mm Hg	>5 days
Respiratory alkalosis, acute	↓ P_{CO_2}	↓ $[HCO_3^-]$	2 mmol/L/10 mm Hg	<6 hours
Respiratory alkalosis, chronic	↓ P_{CO_2}	↓ $[HCO_3^-]$	5 mmol/L/10 mm Hg	>7 days

There are two important pitfalls in the interpretation of the anion gap. First, because the anion gap is proportional to the plasma albumin concentration, hypoalbuminemia (common in critically ill patients) will lower the “baseline” anion gap (by approximately 2.5 mmol/L for each g/dL decline in the albumin concentration).⁷ Thus, profound hypoalbuminemia may falsely lower the anion gap, and thus mask a high anion gap acidosis. Second, alkalemia increases the anion gap by causing lactate generation and by titrating plasma buffers, most notably albumin.⁸ (Thus, in respiratory alkalosis, the bicarbonate concentration will be low in compensation, and the anion gap may be elevated, giving a false impression of a high anion gap metabolic acidosis by inspection of the electrolytes alone.)

If bicarbonate is lost (e.g., through diarrhea), or hydrochloric acid is gained (e.g., renal tubular acidosis or administration of unbuffered amino acid solutions⁹), the bicarbonate concentration falls with a commensurate increase in the plasma chloride concentration; thus the anion gap is unchanged. If, on the other hand, bicarbonate is lost in buffering an organic acid such as lactic acid or a ketoacid, the decrement in the bicarbonate concentration is more or less matched by an increase in the anion gap. These processes are illustrated in Figure 57.1.

Box 57.1 lists the causes of hyperchloremic metabolic acidosis. Two diagnoses are of particular interest in the critical care arena. First is the posthypocapnic metabolic acidosis, in which bicarbonate falls in compensation for a chronic respiratory alkalosis. When “normal” ventilation is restored, the pH falls until bicarbonate can be retained, giving the appearance of a hyperchloremic metabolic acidosis. This emphasizes the importance of observation over time in the analysis of acid-base status. The second entity of interest is a so-called dilutional hyperchloremic acidosis. This is seen in patients who are rapidly resuscitated with large volumes of isotonic saline solution. The acidosis traditionally has been attributed to dilution of blood bicarbonate. Analysis based on physical-chemistry principles may better explain the phenomenon (see later).¹⁰

The differential diagnosis of high anion gap metabolic acidosis is limited (Box 57.2). The most common cause in critically ill patients is a lactic acidosis. The causes of lactic acidosis are numerous. As shown in Box 57.3, they are divided into type A (imbalance between tissue oxygen

demand and supply) and type B (impaired oxygen utilization).⁵ Diabetic ketoacidosis (DKA) (Chapter 58) and intoxications (Chapter 68) are discussed elsewhere. Two causes of high anion gap acidosis recently added to the differential diagnosis, and of particular relevance to intensivists, are *pyroglutamic acidosis* and intoxication with *propylene glycol*.

Pyroglutamic acid is a metabolic intermediate in the γ -glutamyl cycle, one product of which is glutathione. Pyroglutamic acidosis may be congenital (caused by one of several enzyme deficiencies) or acquired.⁸ The acquired syndrome may be caused by acetaminophen (which depletes glutathione, leading to uninhibited pyroglutamic acid synthesis), β -lactam antibiotics, or glycine deficiency. The

 Uremic acidosis

acidosis may be profound and the anion gap greater than 30 mmol/L.¹¹ Definitive diagnosis is made by urinary screen for organic acids. In practice, however, circumstantial evidence suggests the acquired syndrome and the diagnosis is supported by a favorable response to appropriate intervention.

Propylene glycol is a solvent for medications, many of which are commonly infused intravenously in critically ill patients, such as lorazepam, nitroglycerin, etomidate, and phenytoin. Propylene glycol is metabolized by alcohol dehydrogenase to lactic acid. High anion gap acidosis has been associated with high- and even low-dose infusions, particularly of lorazepam.^{7,12} Thus, development of a high anion gap acidosis in a critically ill patient should prompt a search for a source of propylene glycol, because withdrawal of the agent will promptly alleviate the acidosis.

CONSEQUENCES OF ACIDEMIA

It has been generally accepted that severe acidemia (pH < 7.20) is associated with a variety of deleterious effects. Of particular concern are the cardiovascular effects, including pressure-resistant arterial vasodilation, vasoconstriction, diminished myocardial contractility, and impaired hepatic and renal perfusion.¹³ (Some controversy exists as to which of these effects are directly caused by acidemia.⁴) A predisposition to malignant arrhythmias has been reported in vitro and in animal models. Finally, numerous metabolic derangements have been attributed to the effect of acidemia on key enzymes in metabolic pathways, resulting in sympathetic hyperactivity with diminished catecholamine responsiveness; insulin resistance and suppressed glycolysis; and reduced hepatic lactic acid uptake and metabolism.¹⁴

DIAGNOSIS OF ACID-BASE DISORDERS

Acid-base disorders are revealed most commonly through the basic metabolic chemistry panel, when the plasma bicarbonate concentration is noted to be outside the normal range. If the bicarbonate is low, and if the anion gap is clearly elevated on that sample, a diagnosis of high anion gap metabolic acidosis can be made with some confidence, keeping in mind the pitfalls in the interpretation of the anion gap mentioned earlier.⁷

Box 57.3 Causes of Lactic Acidosis**Type A (Tissue Oxygen Supply:Demand Mismatch)**

 D-Lactic Acidosis

If the bicarbonate is low and the anion gap normal, two possibilities exist: either a hyperchloremic metabolic acidosis or a respiratory alkalosis with metabolic compensation. These two entities can be distinguished by examination of the blood pH and blood gases, a low pH being diagnostic of the former.

If the bicarbonate concentration is high, again there are two alternative diagnoses, requiring blood pH measurement for their differentiation: either a metabolic alkalosis or metabolic compensation for a respiratory acidosis.

Once the primary disturbance has been identified, the astute clinician, recognizing the possibility of a mixed disturbance, is obligated to ask, "Is that all there is?" This question can be answered only by an understanding of the rules of normal compensation for simple acid-base disorders (see Table 57.1).² Knowing at least the expected direction of compensation will allow the clinician to diagnose the most

obvious mixed disturbances. For example, if the pH is low, the bicarbonate is low, and the P_{CO_2} is above 40 mm Hg, there is clearly a mixed metabolic and respiratory acidosis. Similarly, if the pH is high, the bicarbonate is high, and the P_{CO_2} is below 40 mm Hg, the diagnosis is a mixed respiratory and metabolic alkalosis. More subtle mixed disorders can be diagnosed only by understanding not only the expected direction, but the expected magnitude of compensation. This will allow one to conclude, for example, whether the hyperventilation in a patient with metabolic acidosis is appropriate (expected compensation), inadequate (a separate respiratory acidosis), or excessive (a separate respiratory alkalosis).

The preceding method permits the diagnosis of simple and dual acid-base disorders. Triple acid-base disorders can be diagnosed only by comparing the change in the anion gap with the change in the plasma bicarbonate concentration. Most simply conceived, the fall in the bicarbonate should equal the rise in the anion gap (see Fig. 57.1). If the rise in the anion gap exceeds the fall in the bicarbonate, a metabolic alkalosis is said to be present in addition to the high anion gap acidosis. Conversely, if the fall in the bicarbonate exceeds the rise in the anion gap, mixed hyperchloremic and high anion gap acidoses are said to coexist. Although this analysis is useful in the case of large discrepancies, in more subtle cases it is confounded by theoretical and practical considerations.^{5,15}

The classical approach to acid-base disorders described earlier has been challenged recently by proponents of a physical-chemistry approach described originally by Stewart.¹⁶ According to this method, the pH of the blood depends on the ionization of water by the difference in the concentration of so-called strong ions (the strong ion difference, or SID). The SID offers a quantitative approach to measuring the degree of acidosis in hyperchloremic metabolic acidosis. Although there is evidence that this approach may offer prognostic capabilities in patients with severe sepsis and septic shock with hyperchloremic metabolic acidosis, the complexity of the equations for calculating the SID may make this method cumbersome in clinical settings.¹⁷ The main utility of this construct in the critical care setting seems to be its explanation of a hyperchloremic metabolic acidosis in patients who receive large volumes of isotonic saline.

TREATMENT OF METABOLIC ACIDOSIS

Treatment of metabolic acidosis is aimed at reversing the adverse consequences of acidemia. Treatment of hyperchloremic metabolic acidosis is straightforward. In cases of acute metabolic acidosis, treatment depends on successful therapy of the underlying cause (e.g., diarrhea) and correction of the bicarbonate deficit, usually in the form of sodium bicarbonate. One can estimate the bicarbonate deficit as follows:

$$\text{HCO}_3^- \text{ deficit} = ([\text{HCO}_3^-]_{\text{final}} - [\text{HCO}_3^-]_{\text{initial}}) \times (\text{volume of distribution of HCO}_3^-)$$

The difficulty in accurately estimating this value arises from two factors: First, the apparent volume of distribution of bicarbonate varies more than twofold—from 50% of body weight to 100% of body weight—and is inversely proportional to the initial bicarbonate concentration.¹⁸ Second,

there are often many simultaneous processes in a critically ill patient that tend to ameliorate or exacerbate the metabolic acidosis, such as vomiting, shock, and liver failure. In order to avoid overshoot alkalemia, it is prudent to estimate the volume of distribution to be 50% of the body weight¹⁴ and to target an increase in the bicarbonate concentration of no more than 8 mmol/L over 12 to 24 hours.

Sodium bicarbonate generally is considered to be the alkalinizing agent of choice for severe acidemia. Alternative alkalinizing agents such as citrate, acetate, and lactate, which under normal circumstances are oxidized in the liver to bicarbonate, should not be used to treat acidemia in patients with suspected or confirmed hepatic impairment or circulatory compromise. The sodium bicarbonate should be administered as a continuous infusion, the concentration of which should be guided by the patient's serum sodium concentration. Bolus injection of undiluted ampules of sodium bicarbonate (1000 mmol/L) should be used with great restraint and only in patients with the most severe acidemia because of the risk of hyperosmolality. Large volumes of any bicarbonate solution can lead to volume overload, a reduction in the ionized calcium concentration (see "Hypocalcemia"), and increased generation of CO_2 . This last effect will tend to cause a respiratory acidosis in patients with ventilatory insufficiency. Plasma electrolytes and blood gases must be monitored frequently to guide adjustments in the composition of the solution and its rate of infusion.

Tris(hydroxymethyl)aminomethane, or THAM, is an amino alcohol that buffers without generating CO_2 . It has the advantage, therefore, of avoiding a superimposed respiratory acidosis. It has been used successfully in animals and humans with various metabolic acidoses.^{13,19} It is eliminated by the kidney, and thus should be used with caution in the setting of renal insufficiency. Risks include hyperkalemia, hypoglycemia, and hepatic necrosis (in neonates).⁷

The treatment of choice for lactic acidosis is reversal of the underlying cause of the acidosis (see Box 57.3). Pending resolution of the underlying disorder, however, the intensivist is often confronted with an unstable patient who is profoundly acidemic. Treatment at this stage is controversial.^{5,13} The debate has focused on the potentially deleterious effects of bicarbonate administration in lactic acidosis.²⁰ In addition to the effects mentioned earlier, bicarbonate in animal models of lactic acidosis has been associated with increased lactate generation, reduction in intracellular pH, increased venous P_{CO_2} , and reduction in cardiac output. (This last effect correlates well with the reduction in ionized calcium concentration.¹³) Studies in humans likewise show no improvement in cardiac output, morbidity rate, or mortality rate with bicarbonate.¹³ Continuous venovenous hemodialysis (e.g., CVVHD) may be a promising tool for treating lactic acidosis, because it provides large amounts of bicarbonate without the risks of volume overload or hypocalcemia. There are several reported cases of successful treatment of metformin-associated lactic acidosis using continuous hemodialysis.^{21,22} Because of its superior short-term clearance compared with continuous renal replacement therapy, however, conventional hemodialysis remains the preferred treatment for metformin intoxication.²³ Treatment of DKA and the acidoses associated with other intoxications are discussed in Chapters 58 and 68, respectively.

METABOLIC ALKALOSIS

DEFINITION AND CLASSIFICATION

Metabolic alkalosis is a process leading to accumulation of extracellular bicarbonate that, if unopposed, will result in an increase in the plasma pH (alkalemia). It can be caused either by a gain of bicarbonate or a loss of fixed acid from the ECF. The causes of metabolic alkalosis have been described.²⁴ In its pure form, it is accompanied by hypoventilation (CO_2 retention).²

From a pathophysiologic perspective, metabolic alkalosis is divided into those factors that generate the alkalosis and those factors that maintain or perpetuate it.^{24,25} Metabolic alkalosis is generated by addition of bicarbonate to the blood. This can occur either by loss of acid from the body or by addition of exogenous alkali. Loss of acid may be from the stomach (e.g., vomiting or nasogastric suction) or kidney. Renal acid loss is enhanced by a high rate of sodium delivery to the distal nephron, high circulating mineralocorticoid levels, potassium depletion, and high rates of ammoniogenesis.

Because of the kidney's prodigious ability to excrete bicarbonate, however, addition of bicarbonate to the blood is not sufficient to cause a sustained metabolic alkalosis. Some mechanism(s) to maintain the alkalosis must prevail. The most common mechanism contributing to the maintenance of metabolic alkalosis is volume depletion, either absolute or relative (e.g., congestive heart failure), which (1) reduces glomerular filtration, (2) enhances tubular bicarbonate reabsorption, and (3) causes secondary hyperaldosteronism, further enhancing urinary acidification. Another common perpetuating factor is potassium depletion, which stimulates proton secretion at several sites along the nephron.²⁴⁻²⁶

Patients with metabolic alkalosis and signs of volume expansion—especially hypertension—usually have excess mineralocorticoid as the explanation for the metabolic alkalosis. Aldosterone and glucocorticoids (other than dexamethasone) stimulate renal loss of acid and potassium, and thereby generate and maintain the alkalosis.

Most cases of clinically significant metabolic alkalosis are maintained by loss of chloride or potassium. Although total body sodium (and hence, volume) derangements are not directly responsible for the generation and maintenance of the metabolic alkalosis, potassium and chloride depletion are commonly seen in settings of volume depletion or excess. Therefore, from a clinical standpoint, it is useful to approach the patient with metabolic alkalosis centering on the history and physical examination, with special attention to the ECF volume status, followed by sequential analysis of blood chemistries.²⁶ Causes of metabolic alkalosis are shown in Box 57.4. One entity unique to critically ill patients is posthypercapnic metabolic alkalosis. This syndrome is caused by abrupt treatment (usually with tracheal intubation and mechanical ventilation) of a chronic respiratory acidosis. The renal bicarbonate retention that compensated for the chronic respiratory acidosis persists (because of volume depletion) after restoration of a normal Pco_2 , resulting in the high pH and high plasma bicarbonate characteristic of metabolic alkalosis. The key to the diagnosis is the history and sequential analysis of blood chemistries.²⁴

CLINICAL CONSEQUENCES

Alkalemia in critically ill patients is associated with increased mortality rate.²⁷ Patients with combined metabolic and respiratory alkalosis have a higher mortality rate than those with respiratory alkalosis alone, and mortality rate in alkalemia is roughly proportional to the pH.²⁷ Although no causal relationship between alkalemia and mortality rate has been established, the pathophysiology of alkalemia is far from benign.²⁵

First, metabolic alkalosis suppresses ventilation, causing CO_2 retention and relative hypoxemia.²⁸ Second, alkalemia acutely increases hemoglobin's oxygen affinity (Bohr effect). Third, respiratory alkalosis causes vasoconstriction, particularly in the cerebral circulation.²⁵ All these processes tend to decrease tissue oxygen delivery.²⁹ (Note that chronic alkalemia inhibits 2,3-diphosphoglycerate synthesis, allowing normalization of the oxyhemoglobin desaturation curve, mitigating tissue hypoxia to some extent.) These alterations in tissue oxygen delivery could be responsible at least in part for some of the clinical manifestations of metabolic alkalosis.

Because alkalemia causes a decrease in ionized calcium concentration (see discussion under “[Calcium Homeostasis](#)”), many of the neuromuscular manifestations of metabolic alkalosis overlap with those of hypocalcemia, including

paresthesias, tetany, and a predisposition to seizures.¹ The acutely diminished tissue oxygen delivery to the brain may contribute to initial confusion and obtundation seen with metabolic alkalosis.

Metabolic alkalosis often is accompanied by hypokalemia and hypomagnesemia. Thus, there is an association between alkalosis and arrhythmias,²⁴ but an independent effect of the alkalosis on cardiac arrhythmogenesis has not been established.

Increases in blood lactate concentration may occur in patients with metabolic alkalosis due to upregulation of phosphofructokinase and thus glycolysis, and because of tissue hypoxia (see earlier).⁸ With severe metabolic alkalosis (arterial pH above 7.55), the tissue hypoxia may be so marked that compensatory hypoventilation will be overridden by hypoxic drive, resulting in a normal to low arterial P_{CO_2} and elevated blood lactate levels (so-called “lactic alkalosis”).³⁰

TREATMENT

Treatment of metabolic alkalosis entails correcting the factor(s) responsible for its maintenance and, if possible, correcting the factor that generated the alkalosis. Once the underlying diagnosis is clear (see Box 57.4), therapy is usually straightforward. If the metabolic alkalosis is maintained by chloride depletion and ECF volume contraction, the intravascular volume should be restored to normal, usually with intravenous isotonic saline.^{24,25} Potassium should be given, as KCl, to replace any deficits (see “Disorders of Potassium Homeostasis”), because potassium depletion perpetuates the metabolic alkalosis. If nasogastric suction cannot be stopped, acid loss can be reduced by the use of H_2 blockers and proton pump inhibitors.

Treating patients with metabolic alkalosis in the setting of volume overload and diminished effective circulating volume (e.g., congestive heart failure, hepatic cirrhosis) is more challenging, because saline infusion is contraindicated. Unless hyperkalemia is present, chloride should be replenished with KCl supplementation. In rare cases of concurrent hyperkalemia, acetazolamide (a carbonic anhydrase inhibitor) may be of benefit as it produces a bicarbonate diuresis. Acetazolamide should be avoided in patients with hypokalemia, because the alkaline diuresis will cause renal potassium wasting.²⁴ Another potential complication of acetazolamide administration, particularly in patients with impending ventilatory failure, is worsening of hypercapnia owing to inhibition of red blood cell carbonic anhydrase and impaired CO_2 transport.²⁵ Hydrochloric acid infusion, as a 0.1 to 0.25 N solution, has been used with success in patients with severe metabolic alkalosis (pH > 7.55 and systemic instability such as encephalopathy or cardiac arrhythmia²⁴) refractory to conventional measures.^{25,31} Correction of the metabolic disturbances has been reported with infusion of 0.25 N HCl at 100 mL/hour over about 12 hours.³¹ Extreme care must be taken to ensure that the infusion catheter is properly positioned within the vena cava, because the solution is highly caustic. Plasma chemistries must be monitored frequently in order to avoid overcorrection. If renal function is severely impaired or medical therapy is not possible, hemodialysis against a low-bicarbonate bath may be used.²⁴

In states of primary mineralocorticoid excess, an aldosterone antagonist such as spironolactone should be used until the underlying abnormality can be corrected. Other potassium-sparing diuretics, such as amiloride and triamterene, are useful as well and are essential in managing the rare patient with Liddle syndrome.

POTASSIUM HOMEOSTASIS

NORMAL POTASSIUM PHYSIOLOGY

Disorders of potassium (K) homeostasis are common in hospitalized patients and may be associated with severe adverse clinical outcomes, including death.^{32,33} Prevention and proper treatment of hyper- and hypokalemia depend on an understanding of the underlying physiology.

The total body potassium content of a 70-kg adult is about 3500 mmol, of which only 2% (about 70 mmol) is extracellular.³⁴ This uneven distribution reflects the large potassium concentration gradient between the intracellular ($K_i \approx 140$ mmol/L) and the extracellular ($K_e \approx 4.5$ mmol/L) space, a gradient that is maintained by the intrinsic ion permeabilities of cell membranes and by Na^+/K^+ -ATPase, the sodium-potassium pump.³⁵ The $K_e:K_i$ ratio largely determines the resting membrane potential of cells and thus is crucial for proper function of excitable tissues (muscle and nerve).³⁵ Small absolute changes in K_e will perturb the ratio significantly. Therefore, disturbances of K_e (measured as changes in plasma potassium concentration, or P_K) may have serious, even fatal, consequences mainly in the form of excitable tissue dysfunction.

It is not surprising, therefore, that the extracellular potassium concentration is tightly regulated. In fact, two separate and cooperative systems participate in potassium homeostasis. One system regulates *external potassium balance*: the total body parity of potassium elimination with potassium intake. The other system regulates *internal potassium balance*: the distribution of potassium between the intracellular and extracellular fluid compartments. This latter system provides a short-term defense against changes in the plasma potassium concentration (P_K) that might otherwise result from total body potassium losses or gains.

REGULATION OF INTERNAL POTASSIUM BALANCE

Internal potassium balance serves to protect against changes in K_e ; potassium tends to move out of cells during potassium depletion and into cells following potassium intake. This process tends to prevent drastic alterations of $K_e:K_i$.^{36,37} The factors that influence internal potassium balance include hormones, acid-base status, plasma tonicity, exercise, and cell integrity (Box 57.5).

The direction and magnitude of an *acid-base*-related change in P_K depend on the nature and the duration of the disturbance. The most consistent and pronounced relationship between changes in pH and P_K occurs in acute mineral (hyperchloremic) acidosis, where there is a strong inverse relationship between these two variables.³⁸⁻⁴⁰ Interestingly, *hypokalemia* is seen with prolonged mineral acidosis in patients with normal renal function and reflects increased renal potassium excretion.³⁹ Unlike mineral acidoses, however, even severe acute organic (high anion gap)

acidoses are not usually associated with hyperkalemia.⁴¹⁻⁴⁴ Indeed, organic acidoses, such as lactic acidosis, actually tend to cause cellular potassium uptake.⁴¹ Nonetheless, factors coincident with the acidosis may alter P_K . For example, mesenteric ischemia may result in both lactic acidosis (from anaerobic metabolism) and hyperkalemia. Even the hyperkalemia so commonly seen in patients with DKA does not result from the acidemia; rather, it appears to be a consequence of the characteristic insulin deficiency and hyperglycemia (see discussion of hypertonicity in the next paragraph).⁴⁴ Respiratory disturbances typically alter P_K less than metabolic disturbances. Alkaloses, respiratory or metabolic, have less effect on P_K than their corresponding acidoses.³⁸ Bicarbonate administration, which was once thought to reduce the P_K by stimulating cellular potassium uptake,⁴⁵ is now known to have very little if any immediate effect on internal potassium balance,^{46,47} except perhaps in patients with preexisting severe metabolic acidosis.⁴¹ It is clear, however, that longstanding alkalemia causes urinary potassium losses that may over time result in profound potassium depletion.⁴⁸

Hypertonicity, as seen with hypertonic fluid administration⁴⁹ or diabetic hyperglycemic states,⁵⁰ leads to hyperkalemia, probably as a result of potassium efflux from cells by way of solvent drag. Fatal hyperkalemia has been attributed to this phenomenon in diabetic patients with end-stage renal disease (ESRD).⁵¹

Exercise causes a transient shift of potassium out of cells. Clinically significant hyperkalemia may result from exercise^{52,53} (and clinically misleading local venous hyperkalemia results from fist clenching during phlebotomy⁵⁴).

REGULATION OF EXTERNAL POTASSIUM BALANCE

In contrast to the prodigious capacity of the kidney to excrete potassium,⁵⁵ renal potassium conservation is imperfect and explains why significant potassium depletion and hypokalemia may result from dietary potassium deficiency alone.⁵⁶

Normally, 90% to 95% of dietary potassium is eliminated through the kidney, and only about 5% to 10% through the intestine. It is the kidney that is almost entirely responsible for matching potassium output to potassium intake in order

to maintain total body potassium constant.⁵⁷ The majority of potassium excreted by the kidney derives from potassium secretion in the distal nephron (connecting tubule and collecting duct).⁵⁷ Virtually all regulation of potassium excretion takes place at this site in the nephron, under the influence of two principal factors: the rate of flow and sodium delivery through that part of the nephron, and the effect of aldosterone.⁵⁷ Potassium secretion is directly proportional to flow rate and sodium delivery through the distal nephron, explaining in part why diuretic use often is accompanied by hypokalemia.

Metabolic acidosis with acidemia results in inhibition of renal potassium secretion.⁴¹ In contrast, metabolic alkalosis and bicarbonate delivery to the distal nephron stimulate kaliuresis by increasing the electrochemical “driving force” for potassium secretion.⁵⁷ Other anions that are poorly reabsorbed in the distal nephron (e.g., synthetic penicillins) have a similar effect to stimulate potassium secretion.⁵⁸

It is well established that aldosterone participates in a homeostatic feedback loop with P_K such that increases in P_K stimulate adrenal aldosterone production, which in turn reduces P_K primarily by stimulating renal potassium excretion.⁵⁷ Hypokalemia is a prominent feature of primary aldosteronism (Conn syndrome) because the high circulating aldosterone levels are accompanied by volume expansion and thus a high rate of sodium delivery to the distal nephron. When circulating aldosterone levels are high due to volume depletion (secondary aldosteronism), the increase in distal potassium secretion is offset by a decrease in distal nephron flow, thus mitigating renal potassium loss. Indeed, it is only when patients with secondary hyperaldosteronism (e.g., in congestive heart failure or hepatic cirrhosis) are treated with diuretic drugs that distal nephron flow is increased and hypokalemia may ensue.

Magnesium deficiency is associated with renal potassium wasting and may result in severe potassium depletion.⁵⁹ Because magnesium, like calcium, acts to stabilize excitable membranes, the deleterious effects of hypokalemia on the myocardium are magnified by concurrent hypomagnesemia (see “Clinical Manifestations” later).⁶⁰

The effect of dexamethasone (a pure glucocorticoid) to enhance renal potassium excretion appears to result entirely from hemodynamic changes that cause an increase in glomerular filtration rate and distal flow rate. All other glucocorticoids tend to further stimulate potassium secretion in proportion to their mineralocorticoid activity.⁵⁷

DISORDERS OF POTASSIUM HOMEOSTASIS

Disorders of potassium homeostasis may be conveniently divided according to the duration of the disturbance: acute (<48 hours’ duration) or chronic. Such a distinction is particularly applicable to the medical intensive care setting where blood chemistries are sampled frequently and a patient’s condition and therapy may change radically over a short time. In addition, the approach to treatment varies according to the acuity of the disturbance. The treatment of acute disturbances is largely independent of their cause, whereas the rational treatment of chronic disturbances depends on understanding their pathogenesis.

ACUTE HYPERKALEMIA (BOX 57.6)**Excessive Potassium Intake**

Given an acute potassium load, a normal individual will excrete about 50% in the urine and transport about 90% of the remainder into cells over 4 to 6 hours.⁶¹ It is possible to overwhelm this adaptive mechanism such that if too much potassium is taken in too quickly, significant hyperkalemia will result. Such events are almost always iatrogenic (i.e., overly aggressive potassium replacement therapy).⁶² One's ability to tolerate a potassium load declines with disordered internal balance (see later) and impaired renal potassium excretory capacity.⁶³ In such circumstances, an otherwise tolerable increase in potassium intake may cause clinically significant hyperkalemia: Doses of oral potassium supplements as small as 30 to 45 mmol have resulted in severe hyperkalemia in patients with impaired external or internal potassium homeostasis.⁶⁴

KCl, used as a supplement, is the drug most commonly implicated in acute hyperkalemia.^{63,65} Banked blood represents a trivial potassium load under most circumstances, because a unit of fresh banked blood, either whole or packed cells, contains only about 7 mmol of potassium.⁶⁶ (The potassium concentration in banked blood does increase substantially as the blood ages, however.⁶⁷) Thus, severe hyperkalemia would result only from massive transfusion of compatible blood.^{67,68} Infants⁶⁹ or patients with renal insufficiency may develop hyperkalemia from an otherwise tolerable transfusion.

Patients undergoing open heart surgery are exposed to cardioplegic solutions containing KCl typically at about 16 mmol/L,⁷⁰ which may lead to clinically significant hyperkalemia in the postoperative period, especially in patients with diabetes mellitus with or without renal failure.⁷¹

Abnormal Potassium Distribution

Acute hyperkalemia may result from sudden redistribution of intracellular potassium to the extracellular space. If only 2% of intracellular potassium were to leak unopposed from cells, P_K would immediately double. Fortunately, such dramatic circumstances are rarely encountered. Nevertheless, smaller degrees of potassium redistribution commonly result in clinically significant hyperkalemia.

Among the most impressive syndromes associated with acute hyperkalemia are those involving *rapid cell lysis*. The *tumor lysis syndrome* results from treatment of chemosensitive bulky tumors with release of intracellular contents, including potassium, into the ECF.⁷² Extreme hyperkalemia even causing sudden death⁷³ has featured prominently in some series of patients. Most of such patients were in renal failure from acute uric acid nephropathy, thus impairing their ability to excrete the potassium load.⁷³ *Rhabdomyolysis*, either traumatic or nontraumatic, may result in sudden massive influx of potassium to the extracellular space.⁷⁴ Hyperkalemia is present in about 40% of patients upon presentation with rhabdomyolysis⁷⁵ and is more common among patients whose course is complicated by oliguric acute renal failure.⁷⁶ Rhabdomyolysis is commonly associated with the use of alcohol⁷⁵ and cocaine.⁷⁷ Extreme hyperkalemia in this latter context has been reported.⁷⁸ Statin drugs are frequently associated with rhabdomyolysis,⁷⁹ rarely causing extreme hyperkalemia.⁸⁰ Other circumstances that may result in redistributive hyperkalemia include severe extensive burns, hemolytic transfusion reactions, and mesenteric ischemia or infarction.

Pharmacologic Agents

Two drugs may rarely cause acute hyperkalemia by redistribution: digitalis glycosides and succinylcholine. Massive digitalis overdose has been associated with extreme hyperkalemia.^{81,82} Succinylcholine depolarizes the motor end plate and in normal individuals causes a trivial amount of potassium leak from muscle, resulting in an increase in P_K by about 0.5 mmol/L.⁸³ In patients with neuromuscular disorders, muscle damage, or prolonged immobilization, however, muscle depolarization may be more widespread, causing severe hyperkalemia.⁸⁴ Prolonged use of nondepolarizing neuromuscular blockers in critically ill patients may predispose to succinylcholine-induced hyperkalemia.⁸⁵

Hyperkalemic Periodic Paralysis

This rare syndrome of episodic hyperkalemia and paralysis is caused by a mutation of the skeletal muscle sodium channel, inherited in an autosomal dominant pattern.⁸⁶ Attacks may be precipitated by exercise, fasting, exposure to cold, and potassium administration, and prevented by frequent carbohydrate snacks. Attacks are usually brief and treatment consists of carbohydrate ingestion. Severe attacks may require intravenous glucose infusions.⁸⁷

Acute Renal Failure

Hyperkalemia accompanies acute renal failure in 30% to 50% of cases. It is seen most commonly in oliguric renal failure. Contributing factors include tissue destruction (e.g., tumor lysis syndrome, rhabdomyolysis) and increased catabolism.⁸⁸

Pseudohyperkalemia

Pseudohyperkalemia refers to a measured potassium level that is higher than that circulating in the patient's blood. It has a number of possible causes. First, it may be caused by efflux of potassium out of blood cells in the test tube after phlebotomy. This may be seen in a *serum* specimen in cases of thrombocytosis⁸⁹ or leukocytosis,⁹⁰ when the clot causes cell lysis in vitro. These days, many clinical laboratories measure electrolytes in plasma (unclotted) specimens. Even under these conditions, extreme leukocytosis may cause pseudohyperkalemia if the specimen is chilled for a long time before the plasma is separated, leading to passive potassium leak from cells.⁹¹ Hemolysis during specimen collection will falsely raise P_K or plasma potassium concentration by liberating intraerythrocyte potassium. Second, if the patient's arm is exercised by fist clenching with a tourniquet in place before the specimen is drawn, the sampled blood potassium concentration will rise significantly as a result of local muscle release of intracellular potassium.⁵⁴

ACUTE HYPOKALEMIA

Hypokalemia that develops over hours is virtually always the result of redistribution of potassium from the extracellular to the intracellular space. The causes of acute hypokalemia are summarized in [Box 57.7](#). Selected causes are discussed as follows.

Treatment of Diabetic Ketoacidosis

It is well recognized that patients presenting in DKA are always severely depleted in total body potassium as a result of glucose-driven osmotic diuresis, poor nutrition, and vomiting during the development of DKA.⁴⁴ Paradoxically, most patients in DKA have a normal P_K upon admission.⁹² Insulin deficiency and hyperglycemia appear to account for the preservation of a normal P_K despite severe total body potassium depletion.⁴⁴ Once therapy for DKA is instituted, however, P_K typically plummets as potassium is rapidly taken up by cells. Potassium replacement at rates up to 120 mmol per hour have been reported, with total potassium supplementation of 600 to 800 mmol within the first 24 hours of

treatment.⁹³ Hypokalemia in this setting may lead to respiratory arrest.⁹⁴

Refeeding

A situation analogous to DKA arises during aggressive refeeding after prolonged starvation or with aggressive “hyperalimentation” of chronically ill patients. The glucose-stimulated hyperinsulinemia and tissue anabolism shift potassium into cells, rapidly depleting extracellular potassium.⁹⁵ Death in the setting of refeeding has been reported and may be partly due to rapid cellular uptake of other ions (e.g., phosphorus, magnesium).⁹⁶

Pharmacologic Agents

Specific β_2 -adrenergic receptor agonists (e.g., albuterol) may cause electrophysiologically significant hypokalemia, especially when given to patients who are potassium depleted from the use of diuretic drugs.⁹⁷ *Epinephrine*, given intravenously in a dose about 5% of that recommended for cardiac resuscitation, causes a fall in P_K by about 1 mmol/L.⁹⁸ Such a dose achieves plasma levels of epinephrine comparable to those seen after acute myocardial infarction and may explain the transient hypokalemia following resuscitation from cardiac arrest even without the use of exogenous epinephrine (postresuscitation hypokalemia).^{99,100} A rare cause of severe hypokalemia is poisoning with *soluble barium salts* such as chloride, carbonate, hydroxide, and sulfide. Soluble barium salts are used in pesticides and some depilatories, which may be ingested accidentally or intentionally.¹⁰¹ Thiopentone, a barbiturate used to induce coma for refractory intracranial hypertension, is associated with redistributive hypokalemia in the majority of treated patients within 12 hours of initiating therapy.¹⁰²

Hypokalemic Periodic Paralysis

Three forms of this rare syndrome have been described: familial, sporadic, and thyrotoxic.^{103,104} All have in common attacks of muscle weakness accompanied by acute hypokalemia caused by cellular potassium uptake. Death may occur due to ventilatory failure or cardiac dysrhythmias. The *familial* variety—resulting from a skeletal muscle calcium channelopathy⁸⁶—is inherited in an autosomal dominant pattern, with onset of clinical manifestations typically in the second decade of life. Attacks may occur after carbohydrate or salt ingestion or exercise. Administration of potassium orally or intravenously will abort an acute attack but is ineffective in preventing attacks.¹⁰³ The *sporadic* variety of hypokalemic periodic paralysis is identical to the familial form except for the absence of a hereditary pattern. *Thyrotoxic* periodic paralysis was first described in Asians but is now recognized to be nearly ubiquitous.¹⁰⁴ The usual onset of symptoms is in the third decade. Severe hypophosphatemia may accompany the hypokalemia.¹⁰⁵ Treatment of the disorder is the same as treatment of hyperthyroidism.

Pseudohypokalemia

Severe leukocytosis may cause spuriously low plasma potassium concentrations if blood cells are left in contact with the plasma for a long time at room temperature or higher. This phenomenon results from ongoing cell metabolism in vitro with glucose and potassium uptake.⁵⁹ Unexpected hypokalemia and hypoglycemia in

CHRONIC HYPERKALEMIA

Renal Failure

Patients with chronic kidney disease tend to maintain a normal P_K until renal function declines to about 10% of normal.¹⁰⁶ Aldosterone and insulin both appear to play a role in the extrarenal potassium adaptation in chronic kidney disease.¹⁰⁷ This explains why patients with chronic kidney disease who are mineralocorticoid or insulin deficient have a particular predisposition to hyperkalemia.¹⁰⁸

Mineralocorticoid Deficiency

Mineralocorticoid deficiency may result from global adrenal insufficiency (*Addison's disease*) or from selective defects in the renin-angiotensin-aldosterone axis (see Chapter 59). Hyperkalemia in the setting of unexplained hypotension should immediately raise one's suspicion for adrenal insufficiency. A common setting for isolated mineralocorticoid deficiency is the syndrome of *hyporeninemic hypoaldosteronism*.¹⁰⁸ This syndrome is most often seen in elderly patients with diabetes mellitus and moderate renal insufficiency. Hyperkalemia is a universal finding. An associated hyperchloremic metabolic acidosis (type IV renal tubular acidosis) is characteristic.¹⁰⁸ In addition to diabetes mellitus, two other systemic diseases are associated with this syndrome: the acquired immunodeficiency syndrome^{109,110} and systemic lupus erythematosus.¹¹¹

Aldosterone deficiency may be induced by a variety of pharmacologic agents acting at different sites in the renin-angiotensin-aldosterone axis. β -Adrenergic receptor blockers and, to a greater extent, *cyclooxygenase inhibitors* (COX-1 and COX-2) predispose patients to hyperkalemia by suppressing renin release.¹¹² As a general rule, COX inhibitors should be avoided in patients with renal insufficiency or who are otherwise prone to hyperkalemia either because of diabetes or the use of other implicated drugs. *Converting enzyme inhibitors* and *angiotensin receptor blockers* decrease aldosterone biosynthesis. These drugs are reported to be implicated in 10% to 38% of hyperkalemia in hospitalized patients.¹¹³ Volume depletion and hypotension increase the risk of hyperkalemia with all these agents.

High- and low-dose *heparin* therapy decreases circulating aldosterone levels by selectively inhibiting aldosterone biosynthesis.¹¹⁴ Hyperkalemia is seen with the use of low-molecular-weight heparins as well, particularly in patients with diabetes mellitus.¹¹⁵

Renal Potassium Secretory Defect

An isolated defect in renal potassium secretion (often with a renal tubular acidosis) is associated with *sickle cell disease* or trait,¹¹⁶ *systemic lupus erythematosus*,¹¹¹ and after *renal transplantation*.¹¹⁷ In this last circumstance, the hyperkalemia is exacerbated by the use of *cyclosporine* and *tacrolimus* for immunosuppression.^{118,119} A syndrome of hyperkalemic (type IV) distal renal tubular acidosis is seen in patients with *urinary tract obstruction*.¹²⁰

The so-called *potassium-sparing diuretics* (spironolactone, eplerenone, amiloride, and triamterene) impair renal potassium excretion by blocking sodium reabsorption in the

distal nephron. Two antibiotics, *pentamidine*¹²¹ and *trimethoprim*,^{122,123} cause hyperkalemia, occasionally severe, by blocking sodium reabsorption in the distal nephron.

CHRONIC HYPOKALEMIA

Chronic hypokalemia is virtually always the result of altered external balance: insufficient potassium intake, excessive potassium losses, or a combination of the two. Losses most often are either GI or renal.

Inadequate Potassium Intake

Because renal potassium conservation is not perfect, severe dietary potassium restriction will cause hypokalemia in 3 to 7 days in normal humans.⁵⁶ In one series of hypokalemic hospitalized patients, inadequate potassium supplementation during intravenous therapy contributed to the development of severe hypokalemia in 45% of cases and was the sole cause in 6%.¹²⁴ Other disorders associated with nutritional hypokalemia include anorexia nervosa, alcoholism, and malignancy.

Excessive Potassium Losses

Hypokalemia may develop as a result of both upper and lower GI fluid losses, but the pathogenesis is quite different in the two situations. With *diarrhea*, the potassium is lost from the gut.¹²⁵ *Gastric fluid losses* (e.g., vomiting or gastric suction) are associated with hypokalemia. Paradoxically, however, most of the potassium losses are renal, not gastric. Gastric fluid potassium concentration is only 5 to 10 mmol/L. Thus, only massive gastric fluid losses would, alone, significantly deplete total body potassium stores. The gastric fluid losses, however, stimulate renal potassium secretion in several ways. First, by generating a metabolic alkalosis and increasing bicarbonate delivery to the distal nephron, potassium secretion is stimulated. The metabolic alkalosis also leads to cellular proton loss and potassium uptake that, in renal epithelial cells, enhances potassium secretion. Finally, the volume contraction that usually accompanies GI fluid losses causes secondary aldosteronism, which further augments urinary potassium losses. Thus, in this situation, urinary potassium concentration is typically high while urinary chloride concentration is low due to volume contraction. (Urinary sodium losses may be high because of natriuresis obligated by the bicarbonaturia.)

All *diuretics* work by inhibiting sodium and chloride reabsorption by the nephron. Those drugs that act proximal to the potassium secretory site in the nephron promote a kaliuresis by increasing delivery of fluid distally and causing secondary aldosteronism. Thus, hypokalemia frequently accompanies the use of the two most common classes of diuretics: thiazides and loop diuretics.¹²⁶ Carbonic anhydrase inhibitors exert an additional kaliuretic effect by shunting bicarbonate-rich, chloride-poor fluid to the distal nephron.¹²⁷ Combining two potassium-wasting diuretics for added diuretic effect (e.g., furosemide plus metolazone) can result in severe hypokalemia. In such cases, P_K has been found to fall below 3.5 mmol/L in over 80% of patients and below 3.0 mmol/L in more than half.¹²⁶

Various antibiotic agents may cause renal potassium wasting and thereby hypokalemia; 90% of patients receiving *amphotericin B* require potassium supplementation.¹²⁸ *Penicillin* antibiotics, particularly polyanionic derivatives such as

carbenicillin and ticarcillin, have been associated with hypokalemia.¹²⁹

Mineralocorticoids predispose to hypokalemia by stimulating renal potassium excretion. Mineralocorticoid excess may be *primary*¹³⁰ (Conn syndrome) or *secondary* to diminished real or “effective” circulating volume. All glucocorticoid drugs except dexamethasone possess some mineralocorticoid activity. Therefore, prolonged administration of these agents can cause severe hypokalemia. In edematous patients with secondary aldosteronism (e.g., congestive heart failure, hepatic cirrhosis) hypokalemia commonly ensues only when diuretic therapy enhances distal nephron flow rate.

Magnesium deficiency is associated with renal potassium wasting and may result in severe potassium depletion (see later). Because magnesium, like calcium, acts to stabilize excitable membranes, the deleterious effects of hypokalemia on the myocardium are magnified by concurrent hypomagnesemia.¹³¹ The intensive care setting is fraught with potential causes of hypomagnesemia (see discussion under “[Magnesium Homeostasis](#)”).

Hypercalcemia causes a salt and water diuresis and is therefore commonly associated with renal hypokalemia (see “[Calcium Homeostasis](#)”).¹³² In one series, one third of hypercalcemic patients were hypokalemic with no other predisposing factors; the prevalence was 52% in patients with hypercalcemia of malignancy. P_K was inversely proportional to the plasma calcium concentration.¹³³

Several inborn tubular transport abnormalities are associated with chronic hypokalemia (and metabolic alkalosis). *Bartter* and *Gitelman* syndromes are associated with volume contraction and normal blood pressure, and *Liddle* syndrome with hypertension.¹³⁴

CLINICAL MANIFESTATIONS OF POTASSIUM IMBALANCE

Alterations in P_K have a variety of adverse clinical consequences, the expression of which may be magnified in the critically ill patient. The most serious of these manifestations are those involving excitable tissues.

CLINICAL MANIFESTATIONS OF HYPERKALEMIA

Cardiac Effects

Hyperkalemia depolarizes the cell membrane, slows ventricular conduction, and decreases the duration of the action potential. These changes produce the classic electrocardiogram (ECG) manifestations of hyperkalemia including (in order of their usual appearance) peaked T waves, prolongation of the PR interval, widening of the QRS complex, loss of the P wave, “sine wave” configuration or ventricular fibrillation, and asystole.^{135,136} These ECG changes may be modified by a multitude of factors such as ECF, pH, calcium concentration, sodium concentration, and the rate of rise of P_K .¹³⁵

ECG changes may not accompany changes in P_K . If present, these ECG changes certainly suggest hyperkalemia. However, in the absence of the classic ECG changes, the clinician should not be lulled into a false sense of security when evaluating a hyperkalemic patient. Normal ECGs occur despite extreme hyperkalemia,¹³⁷ and the first cardiac

manifestation of hyperkalemia may be ventricular fibrillation.¹³⁸ Consequently, P_K greater than 6.5 mmol/L, even with a normal ECG, should be treated as an emergency (see “[Treatment of Potassium Imbalance](#)”).

Neuromuscular Effects

Hyperkalemia may result in paresthesias and weakness progressing to a flaccid paralysis, which typically spares the diaphragm. Reflexes are depressed or absent. Cranial nerves are rarely involved and sensory changes are minimal.¹³⁹

Metabolic Effects

Hyperkalemia decreases renal ammoniogenesis, which by itself may produce a mild hyperchloremic metabolic acidosis¹⁴⁰ and will limit the kidney’s ability to excrete an acid load and thus prevent correction of a metabolic acidosis.¹⁴¹

CLINICAL MANIFESTATIONS OF HYPOKALEMIA

Although less immediately life threatening than hyperkalemia, hypokalemia has many detrimental effects in critically ill patients. Along with cardiac and neuromuscular manifestations are many more subtle effects.

Cardiac Effects

Hypokalemia hyperpolarizes the cell membrane and prolongs the cardiac action potential.¹⁴² These changes are associated with the following ECG manifestations: ST-segment depression, a decrease in T-wave amplitude, and an increase in U-wave amplitude.^{135,136} However, because all of these changes are nonspecific, the ECG is an even less reliable index of hypokalemia than it is of hyperkalemia.

Hypokalemia may be associated with an increased incidence of arrhythmias and conduction defects. It is well established that potassium depletion increases the cardiac toxicity of digitalis glycosides.¹⁴³ However, controversy exists as to whether hypokalemia per se induces ventricular arrhythmias in patients not taking digitalis. There is an increase in benign ventricular ectopy in hypokalemic patients without acute myocardial ischemia.¹⁴⁴ The clinical importance of this observation is unclear. In individuals hospitalized with acute myocardial infarction, however, a correlation between hypokalemia and ventricular tachycardia and fibrillation was observed.¹⁴⁵ Because potassium repletion did not reduce the occurrence of these arrhythmias, it is unlikely that hypokalemia was the sole arrhythmogenic factor.¹⁴⁵ A recent study of patients presenting with acute myocardial infarction showed a U-shaped relationship between mean in-hospital P_K and mortality rate, such that P_K less than 3.5 mmol/L or greater than 4.5 mmol/L were each associated with higher in-hospital mortality rates. The lowest mortality rate was seen in patients with P_K 3.5 to 4.0 mmol/L, implying that potassium supplementation to achieve higher concentrations was not justifiable.¹⁴⁶

Neuromuscular Effects

Modest hypokalemia generally presents as weakness, myalgias, muscle fatigue, and “restless” legs. With more severe hypokalemia (less than 2 mmol/L), paralysis may supervene. This usually involves the extremities but may progress to include the trunk and muscles of ventilation. As with hyperkalemia, cranial nerves typically are spared and sensory function usually remains intact.⁵⁹ It is important to note that

these manifestations may be masked by concomitant hypocalcemia and may only appear when calcium is replenished. Conversely, in patients with hypokalemia and hypocalcemia, tetany may develop only after potassium replacement.⁵⁹ Smooth muscle dysfunction (ileus, gastroparesis) is more commonly seen with hypokalemia than with hyperkalemia.

In addition to the effects of potassium depletion on the electrical properties of the neuromuscular system, profound hypokalemia may result in muscle injury and frank rhabdomyolysis, even in bed-bound patients.¹⁴⁷

Miscellaneous Effects

Hypokalemia and potassium depletion are associated with glucose intolerance,¹⁴⁸ increased protein catabolism, polydipsia and polyuria,⁵⁹ and metabolic alkalosis.¹⁴⁹

EVALUATION OF DISORDERS OF POTASSIUM HOMEOSTASIS

The diagnostic approach to disorders of potassium homeostasis may be focused by dividing them according to their duration: acute (or of unknown duration) versus chronic.

EVALUATION OF ACUTE HYPERKALEMIA

When P_K rises abruptly or if P_K is high (greater than 6.5 mmol/L) on initial presentation of the patient, the first step is to obtain an ECG to look for electrophysiologic evidence of hyperkalemia. In the presence of such signs, treatment for hyperkalemia should begin urgently (see “Treatment of Potassium Imbalance”). At the same time, an unclotted blood sample should be obtained, using meticulous phlebotomy technique, for another set of electrolytes, glucose, blood urea nitrogen (BUN) and creatinine, and complete blood count (CBC). Urine should be tested for heme pigments to exclude acute rhabdomyolysis or hemolysis. The patient’s list of medications and diet should be reviewed promptly, looking for exogenous sources of

potassium and drugs that may impair potassium tolerance (see Box 57.6).

EVALUATION OF CHRONIC HYPERKALEMIA

Figure 57.2 outlines an approach to the patient with hyperkalemia lasting for days. Failure to stimulate cortisol release with a cosyntropin stimulation test (see Chapter 59) supports a diagnosis of Addison’s disease. Absent that diagnosis, the patient is likely to have either selective aldosterone deficiency or tubular unresponsiveness to aldosterone. Assessment of the renin-angiotensin-aldosterone axis is most simply done by measuring plasma renin activity (PRA) and aldosterone levels in the basal and diuretic/posture-stimulated state.¹⁰⁸ Tubular unresponsiveness to aldosterone is assessed by measuring the potassium secretory effect of 9 α -fludrocortisone (9 α -F, Florinef). One index of the driving force for potassium secretion that may be useful in this regard is the transtubular potassium gradient (TTKG), calculated as follows:

$$TTKG = \frac{U_K}{P_K} \times \frac{P_{osm}}{U_{osm}}$$

where P_{osm} and U_{osm} are plasma and urine osmolalities, respectively.¹⁵⁰ A spot urine potassium:creatinine ratio may be used instead of the TTKG.

EVALUATION OF ACUTE HYPOKALEMIA

Hypokalemia accompanied by serious cardiac or neuromuscular manifestations is an emergency. Likewise, urgent therapy is indicated for profound hypokalemia (P_K less than 2.0 mmol/L) even in the absence of clinical complications. In addition, moderate hypokalemia (P_K less than 3.0 mmol/L) in patients taking digitalis,¹⁴³ and perhaps with acute myocardial ischemia,¹⁴⁵ should be treated urgently because of the risk of ventricular arrhythmias. In all these situations, it is imperative that the blood specimen be

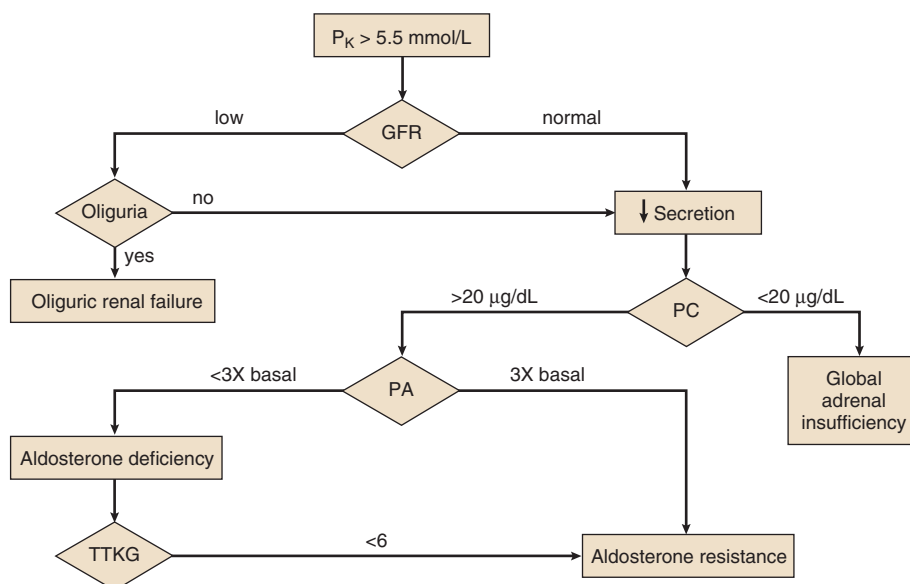

Figure 57.2 Diagnostic evaluation of chronic hyperkalemia. GFR, glomerular filtration rate; PA, stimulated plasma aldosterone (see text); PC, stimulated plasma cortisol (see Chapter 59); TTKG, transtubular potassium gradient (see text).

obtained and handled properly, especially in patients with leukocytosis, because rapid administration of potassium to a patient with pseudohypokalemia may cause severe hyperkalemia.

The remainder of the evaluation of acute hypokalemia derives mainly from the patient's history, with an emphasis on treatments causing cellular potassium uptake (e.g., insulin, β -adrenergic agonists) or a rapid increase in tissue anabolism, and a history of periodic paralysis. Patients who are hypokalemic upon presentation should be evaluated as though their hypokalemia were acute.

EVALUATION OF CHRONIC HYPOKALEMIA

Once acute hypokalemia and transient potassium redistribution have been excluded, one should next determine whether the kidney is responding appropriately to the potassium deficit or whether it is contributing to the problem. This is best done by measuring the 24-hour urinary excretion of potassium during potassium repletion (Fig. 57.3). Potassium excretion less than 20 mmol per day suggests appropriate renal potassium conservation and points to extrarenal (lower GI or skin) potassium losses, recovery from diuretic-induced hypokalemia, or chronically potassium-deficient diet. Excretion of greater than 20 mmol per day is evidence of inadequate renal potassium conservation indicating a renal cause of the hypokalemia. Renal potassium losses associated with normal systemic blood pressure are most commonly seen with the use of thiazide or

loop diuretics and are accompanied by a metabolic alkalosis. Other causes of hypokalemia with metabolic alkalosis in a normotensive patient include gastric fluid loss and Bartter and Gitelman syndromes. These are separable most often by history, but if not, the urinary chloride measurement will be helpful, being low with gastric fluid losses. Renal hypokalemia may accompany a renal tubular acidosis, in which case the plasma bicarbonate will be low.

Mineralocorticoid excess may be the cause if the renal potassium loss is associated with systemic hypertension, and the renin-aldosterone axis should be studied with basal and saline-suppressed blood hormone measurements. High PRA and aldosterone levels suggest renal artery stenosis, malignant hypertension, or rarely a renin-secreting tumor. Low PRA and high aldosterone levels indicate primary aldosteronism. When both PRA and aldosterone levels are low, one should suspect the syndrome of apparent mineralocorticoid excess, Cushing syndrome, or rarely Liddle syndrome. Note that Cushing syndrome due to ectopic adrenocorticotrophic hormone (ACTH) secretion often is not accompanied by typical cushingoid features.¹⁵¹

TREATMENT OF POTASSIUM IMBALANCE

In general, the initial treatment of acute severe potassium imbalance is independent of the cause of the disturbance, whereas the rational therapy for chronic hyper- or hypokalemia depends on an understanding of its pathogenesis.

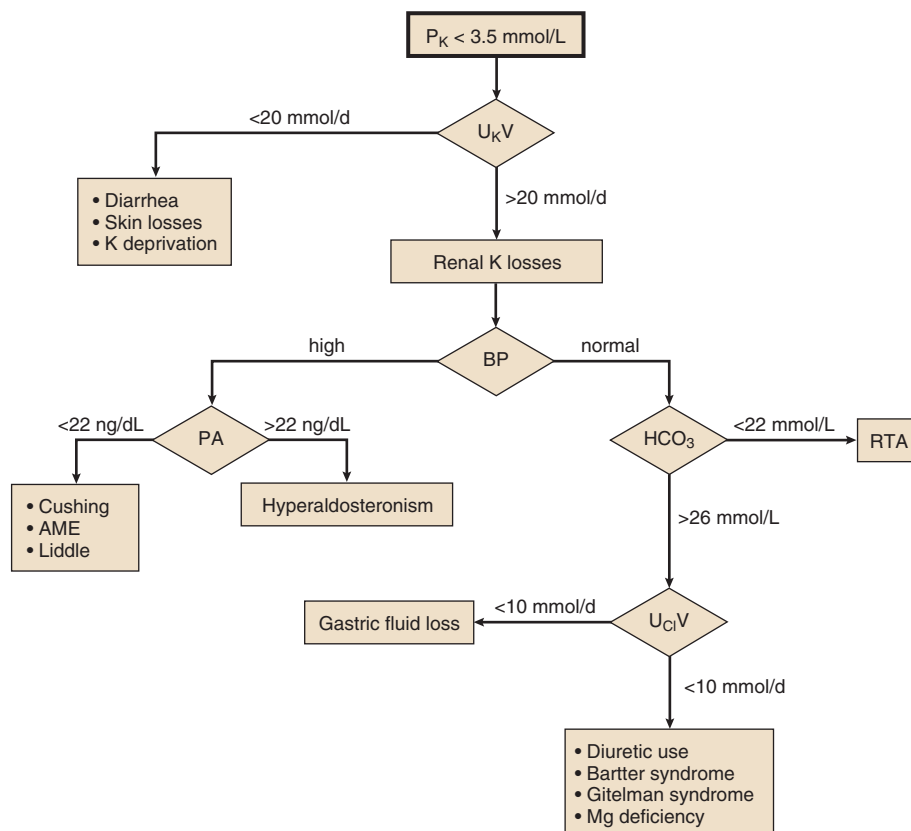

Figure 57.3 Diagnostic evaluation of chronic hypokalemia. AME, syndrome of apparent mineralocorticoid excess; BP, blood pressure; PA, stimulated plasma aldosterone (see text); RTA, renal tubular acidosis; U_{ClV} , urinary chloride excretion; U_{KV} , urinary potassium excretion.

TREATMENT OF ACUTE HYPERKALEMIA

In considering when hyperkalemia constitutes an emergency, two points should be kept in mind. First, the electrophysiologic effects of hyperkalemia are directly proportional to both the absolute P_K and its rate of rise.¹³⁵ Second, although the ECG manifestations of hyperkalemia are generally progressive and proportional to the P_K , ventricular fibrillation may be the first ECG disturbance of hyperkalemia;¹³⁸ conversely, a normal ECG may be seen with extreme hyperkalemia.¹³⁷ Thus, it is apparent that neither the ECG nor the P_K alone is an adequate index of the urgency of hyperkalemia, and that the clinical context must be considered when assessing a hyperkalemic patient. Because most patients manifest hyperkalemic ECG changes at P_K greater than 6.7 mmol/L,¹³⁶ hyperkalemia should be treated emergently for (1) P_K greater than 6.5 mmol/L and (2) ECG manifestations of hyperkalemia regardless of the P_K .¹⁵²

Therapy of acute or severe hyperkalemia is directed at preventing or ameliorating its untoward electrophysiologic effects on the myocardium. The goals of therapy, in chronological order, are as follows (Table 57.2):

1. Antagonize the effect of potassium on excitable cell membranes.
2. Redistribute extracellular potassium into cells.
3. Enhance elimination of potassium from the body.

Membrane Antagonism

Calcium. Calcium directly antagonizes the myocardial effects of hyperkalemia without lowering P_K .¹⁵³ During treatment with calcium, the ECG should be monitored continuously. The dose may be repeated in 5 minutes if there is no improvement in the ECG, or if the ECG deteriorates after

an initial improvement.¹⁵² There are several case reports of sudden death in patients given intravenous calcium while also receiving digitalis glycosides.¹⁵⁴ Although these observations do not provide clear guidance, it may be wise to administer intravenous calcium with caution to patients known or strongly suspected of having toxic levels of digitalis glycosides.

Hypertonic Saline. Intravenous hypertonic sodium chloride has been shown to reverse the ECG changes of hyperkalemia in patients with concurrent hyponatremia.¹⁵⁵ Whether hypertonic saline is effective in the treatment of eunatremic patients has not been established. Moreover, the extracellular volume load imposed by hypertonic saline argues against its use.

Redistribution of Potassium into Cells

Insulin. Insulin reliably lowers P_K in a dose-dependent manner. An intravenous dose of 10 units of regular insulin given as a bolus along with an intravenous bolus of dextrose (25-40 g as a 50% solution) to adult patients lowers the P_K by about 1 mmol/L.^{156,157} After the initial bolus, a dextrose infusion should be started, because a single bolus of 25 g of dextrose has been shown to be inadequate to prevent hypoglycemia at 60 minutes.¹⁵⁶ There seems to be no advantage of a continuous insulin infusion over a bolus injection.⁴⁰ Insulin should be used without dextrose in hyperglycemic patients; indeed, the cause of the hyperkalemia in those patients may be the hyperglycemia itself.⁵⁰

Albuterol. P_K has been shown to decline by 0.6 mmol/L after inhalation of 10 mg of albuterol, and by about 1.0 mmol/L after 20 mg in patients with ESRD.¹⁵⁸ The effect of insulin is additive with that of albuterol, with the

Table 57.2 Emergency Treatment of Hyperkalemia

Agent/Intervention	Dose	Onset	Duration	Complications
Membrane Stabilization				
Calcium gluconate (10%)	10 mL IV over 10 min	Immediate	30-60 min	Hypercalcemia
Hypertonic (3%) sodium chloride	50 mL IV push	Immediate	Unknown	Volume overload Hypertonicity
Redistribution				
Insulin (short-acting)	10 units IV push, with 25-40 g dextrose (50% sol'n)	20 min	4-6 h	Hypoglycemia
Albuterol	20 mg in 4 mL normal saline solution, nebulized over 10 min	30 min	2 h	Tachycardia Inconsistent response
Elimination				
Loop diuretics				
Furosemide	40-80 mg IV	15 min	2-3 h	Volume depletion
Bumetanide	2-4 mg IV			
Sodium bicarbonate	150 mmol/L IV at variable rate	Hours	Duration of infusion	Metabolic alkalosis Volume overload
Sodium polystyrene sulfonate (SPS) (Kayexalate, Kionex)	15-30 g in 15-30 mL 70% sorbitol PO	>2 h	4-6 h	Variable effect Intestinal necrosis
Hemodialysis		Immediate	3 h	Arrhythmias

combination reported to result in a decline in P_K by about 1.2 mmol/L at 60 minutes.¹⁵⁶ Even among patients not taking beta blockers, as many as 40% appear to be resistant to the hypokalemic effect of albuterol.^{156,158} For that reason, albuterol should never be used alone for the treatment of urgent hyperkalemia.

Bicarbonate. The putative benefits of a bolus injection of sodium bicarbonate in the emergency treatment of hyperkalemia pervaded the literature until the past decade. Ironically, this dogma was based on studies using a prolonged (4–6 hours) infusion of bicarbonate.⁴⁵ It has now been clearly demonstrated that short-term bicarbonate infusion does not reduce P_K in patients with dialysis-dependent kidney failure, implying that it does not cause potassium shift into cells.^{46,47,159}

Elimination of Potassium from the Body

Enhanced Renal Elimination. Hyperkalemia occurs most often in patients with renal insufficiency. However, renal potassium excretion may be enhanced even in patients with moderate renal failure by increasing distal nephron flow. This may be accomplished with *saline* or *sodium bicarbonate infusions* and may be enhanced further by the use of *loop diuretics*. Diuretic-induced volume contraction must be avoided because this will lead to decreased distal nephron flow and reduced potassium excretion.¹⁵²

Exchange Resin. Sodium polystyrene sulfonate (SPS, Kayexalate, Kionex) is a cation exchange resin that exchanges sodium for secreted potassium in the colon. Each gram of resin binds approximately 0.65 mmol of potassium in vivo, although the effect is highly variable and unpredictable.⁴⁰ The resin causes constipation and hence almost always is given with a cathartic. It is more effective when given orally than by retention enema.⁴⁰

There are two concerns with the use of SPS for the treatment of urgent hyperkalemia. The first is its slow effect. When given orally, the onset of action is at least 2 hours and the maximum effect may not be seen for 6 hours or more. One recent study in hemodialysis patients failed to show any effect on P_K after an oral dose of SPS.¹⁶⁰ The second concern with SPS is its possible toxicity. There are numerous case reports of patients who developed intestinal necrosis after exposure to SPS in sorbitol as an enema^{161–163} and orally.¹⁶⁴ A retrospective study estimated the incidence of colonic necrosis to be 1.8% among postoperative patients.¹⁶⁴ For these reasons, some authorities consider the use of SPS to be unjustifiable.¹⁶⁵

Dialysis. Hemodialysis is the dialytic method of choice for removal of potassium from the body. P_K falls by over 1 mmol/L in the first 60 minutes of hemodialysis and a total of 2 mmol/L by 180 minutes, after which it reaches a plateau.⁴⁰ Rebound always occurs after dialysis, with 35% of the reduction abolished after an hour and nearly 70% after 6 hours.⁴⁰ There is controversy as to whether dialysis for severe hyperkalemia precipitates serious ventricular arrhythmias. Because of the possibility, patients dialyzed for severe hyperkalemia should have continuous ECG monitoring.⁴⁰ The rate of potassium removal with *peritoneal dialysis* is much slower than with hemodialysis.⁴⁰

TREATMENT OF CHRONIC HYPERKALEMIA

As established previously, chronic hyperkalemia always implies deficient renal potassium excretion. It follows that the therapy of chronic hyperkalemia is primarily directed toward stimulating renal potassium excretion while limiting potassium intake. For all adults with chronic hyperkalemia, daily potassium intake should be restricted to 60 mmol. All drugs known to impair either internal or external potassium balance should be eliminated if possible. Finally, all patients with chronic hyperkalemia should be evaluated for occult urinary tract obstruction.

Further therapy of the persistently hyperkalemic patient should be guided by the diagnostic evaluation outlined in [Figure 57.2](#). In cases of mineralocorticoid unresponsiveness or when mineralocorticoid treatment is complicated by fluid overload, a *thiazide* or *loop diuretic* can be added to the regimen. This will restore normal volume status and enhance renal tubular potassium secretion in many mineralocorticoid-resistant patients. It is crucial to avoid diuretic-induced volume depletion, however, because this will exacerbate the renal potassium secretory defect.

Patients who fail to respond to the previously mentioned measures with an increase in TTKG or urine potassium:creatinine ratio and a decrease in P_K may be given sodium bicarbonate, which will stimulate renal potassium secretion. This is especially appropriate for patients whose chronic hyperkalemia is accompanied by a renal tubular acidosis (type IV RTA). The usual dose is 1 to 2 mmol bicarbonate per kg body weight per day in three or four divided doses.¹⁵²

TREATMENT OF ACUTE HYPOKALEMIA

A low P_K almost always indicates a large total body potassium deficit. In fact, P_K decreases by approximately 0.3 mmol/L for each decrement of 100 mmol total body potassium.¹⁶⁶ But if potassium is replenished too quickly, the homeostatic mechanisms that defend P_K will be overwhelmed and P_K will rise abruptly. The rate of rise of P_K with potassium administration can be greatly altered by factors that affect internal potassium balance. For example, during treatment of DKA with insulin, cellular uptake of potassium may be massive, obligating enormous replacement doses of potassium. Conversely, insulin deficiency markedly impairs tolerance to a potassium load.⁶¹

See “[Evaluation of Acute Hypokalemia](#)” for definitions of urgent hypokalemia. Limited information exists on which to base a rational prescription of KCl in an emergency.^{61,167,168}

Based on the available literature, we can estimate that nondiabetic patients with normal renal function should respond well to a 1- to 2-hour infusion of KCl at 0.6 mmol/kg/hour given intravenously in saline. In patients with renal failure of any degree, the infusion rate should be halved (0.3 mmol/kg/hour). Patients with diabetes mellitus not being treated for DKA or hyperglycemia should receive no more than 0.2 mmol/kg/hour, or about 0.1 mmol/kg/hour in the setting of renal failure. For severe hypokalemia, the ECG should be monitored continuously and the infusion stopped immediately if signs of hyperkalemia develop. The maximum increase in P_K is seen at the end of the infusion, and about 50% of the increase is lost over the next 2 to 3 hours when a new steady state is achieved. Thus, P_K

should be measured at the end of the infusion. If the patient is still dangerously hypokalemic at this point, additional potassium may be given. If at the end of the infusion P_K is in an acceptable range, the measurement should be repeated 2 to 3 hours later when disposal of potassium load is complete in order to determine the need for further treatment.¹⁵²

Hypokalemia in the setting of aggressive “refeeding,” and especially in the treatment of severe DKA, should be treated initially as described earlier. Frequent monitoring of P_K with rapid laboratory turnaround time is critical for proper management.

Hypokalemia that is not life threatening is best treated with oral potassium replacement. It is important to recognize that GI absorption of an oral dose of KCl elixir is essentially complete. Dangerous hyperkalemia can occur in entirely normal individuals following KCl ingestion.¹⁶⁹ The maximum increase in P_K is seen 1.5 to 2 hours after an oral potassium load. Thus, a sensible oral dose of KCl in moderate hypokalemia should probably not exceed the hourly intravenous doses proposed earlier. There is no reason to give a simultaneous oral and intravenous potassium dose; serious hyperkalemia may ensue.

TREATMENT OF CHRONIC HYPOKALEMIA

The treatment of chronic hypokalemia depends entirely on identifying and, if possible, remediating the cause (see Fig. 57.3). When the cause of the excessive potassium loss cannot be treated specifically, maintenance potassium supplementation is needed.

WATER HOMEOSTASIS

Hyponatremia and hypernatremia reflect disorders of water homeostasis. They are common disorders in critically ill patients and are associated with increased morbidity and mortality rates.^{170,171}

PHYSIOLOGY OF WATER HOMEOSTASIS

Normal plasma sodium concentration varies very little, even less than the “normal” range of clinical laboratories (135–145 mmol/L). This tight regulation depends on the following elements: (1) pituitary secretion of arginine vasopressin (AVP; also known as antidiuretic hormone, or ADH) that varies over a wide range in response to physiologic stimuli; (2) kidneys that are capable of responding to circulating vasopressin by varying the urine concentration; (3) intact thirst; and (4) access to water.

Tonicity or *effective osmolality* describes the capacity of particles in solution to effect water movement across a semipermeable membrane such as the cell membrane. The normal response to water ingestion (of sufficient magnitude to lower the plasma osmolality even slightly) is the excretion of maximally dilute urine (urine osmolality <100 mOsm/kg). The underlying physiologic sequence is as follows: The plasma *hypotonicity* is sensed by the cells making up the hypothalamic osmostat. These hypothalamic nuclei then proportionately reduce their synthesis of AVP, also known as ADH, leading to diminished AVP release into the circulation by the posterior pituitary. The lower circulating AVP

concentration, in turn, results in the insertion of proportionately fewer water channels into the collecting duct of the kidney. This, in turn, creates a more water-impermeable conduit, preventing water reabsorption and allowing excretion of the dilute urine elaborated by the more proximal segments of the nephron.¹⁷²

Conversely, plasma hypertonicity leads to higher circulating AVP concentration and proportionately higher water permeability of the collecting duct, and the excretion of a concentrated urine.¹⁷²

Figure 57.4 shows the relationship between plasma osmolality, plasma AVP concentration, and urine osmolality. The normal “set point” is a plasma osmolality of about 285 mOsm/kg. Notice that the minimum urine osmolality is about 50 mOsm/kg, and the maximum is about 1200 mOsm/kg.¹⁷³

When plasma osmolality rises beyond 290 to 295 mOsm/kg, the *thirst* center of the hypothalamus is stimulated. At that point, neurologically intact individuals with access to water will drink until the plasma osmolality returns to normal.¹⁷³

NONOSMOTIC VASOPRESSIN RELEASE

It is important to recognize that plasma osmolality is not the only determinant of AVP synthesis and release. Low arterial blood pressure and low effective arterial volume powerfully stimulate AVP release.¹⁷³ This baroreceptor-mediated AVP release is teleologic, because water retention is an important component in the defense against hypovolemia. So primal is this circulatory defense that the baroreceptor stimulation predominates over any osmolal effect on AVP release.¹⁷³ Thus, a volume-contracted or hypotensive individual will have high circulating AVP levels even if his plasma osmolality is low. In addition, circulating AVP levels rise with pain, stress, nausea, hypoxia, hypercapnia, and a variety of medications, most notably epinephrine and high doses of narcotic analgesics.¹⁷³

Figure 57.4 Typical example of the relationship between plasma osmolality (P_{OSM}), plasma vasopressin concentration (P_{AVP}), and urine osmolality (U_{OSM}). P_{AVP} and U_{OSM} vary around the *set point* to maintain P_{OSM} within the range of normal.

HYPONATREMIA

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

Hyponatremia (plasma sodium concentration < 135 mmol/L) is one of the most common electrolyte disorders, found in approximately 3% of hospitalized patients and as many as 30% of patients in ICUs.¹⁷⁰

The clinical manifestations of hyponatremia are largely attributed to intracellular volume expansion (cellular edema), which occurs only when hyponatremia is associated with hypotonicity. Intracellular volume expansion is of greatest consequence in the brain, where it is translated into increased intracranial pressure because of the rigid calvarium.¹⁷⁴

PATHOPHYSIOLOGY

The pathophysiology of hypotonic hyponatremia has important implications for its management. Most cells—especially brain cells—have adaptive mechanisms for mitigating tonicity-related volume changes.¹⁷⁴ Cell volume peaks 1 to 2 hours after the onset of acute hypotonicity. Thereafter, solute and water are lost from cells, and cell volume returns toward normal. After several days of sustained hypotonicity, cell volume is restored nearly to normal.¹⁷⁴

The morbidity and mortality risks associated with hypotonic hyponatremia are influenced by several factors, including the magnitude and rate of development of the hyponatremia, the patient's age and gender, and the nature and severity of any underlying diseases.¹⁷⁴ The very young and very old, women, and alcoholics appear to be at particular risk.¹⁷⁵ Cell-volume adaptation to hypotonicity may be deficient in premenopausal women, who suffer more frequent and more severe neurologic consequences than men with equivalent degrees of hypotonicity.¹⁷⁶

Neurologic symptoms usually do not occur until the plasma sodium concentration falls below 125 mmol/L, at which point the patient may complain of anorexia, nausea, and malaise. Between 120 and 110 mmol/L, headache, lethargy, confusion, agitation, and obtundation may be seen. More severe symptoms (seizures, coma) may occur with levels below 110 mmol/L.¹⁷⁷ Focal neurologic findings are unusual but do occur, and transtentorial cerebral herniation has been described in severe cases, especially in young women following surgery.¹⁷⁶ In that setting, hypoxemia is common and often is associated with noncardiogenic pulmonary edema.¹⁷⁸ Hypoxia appears to exacerbate the cerebral damage in hyponatremia.¹⁷⁹

Although symptoms generally resolve with correction of the hypotonicity, permanent neurologic deficits may occur, particularly in acute severe hypotonicity, when the brain's volume-regulatory defenses may be overwhelmed.¹⁷⁶ Profound hypotonicity that develops in less than 24 hours may be associated with residual neurologic deficits and has a 50% mortality rate in some populations.¹⁷⁶ In contrast, when hypotonicity develops more gradually, symptoms are both less common and less severe. Indeed, patients with chronic hyponatremia, even in the range of 115 to 120 mmol/L, may be completely asymptomatic.¹⁷⁴

DIFFERENTIAL DIAGNOSIS

Hyponatremia may coexist with a normal, high, or low plasma osmolality. Thus, the diagnostic algorithm for

hyponatremia (see Fig. 57.2) begins with an assessment of the plasma osmolality (P_{osm}). This may be estimated by the following formula:

$$\text{estimated } P_{\text{osm}} = (2 \times P_{\text{Na}}) + \frac{P_{\text{gluc}}}{18} + \frac{\text{BUN}}{2.8}$$

where P_{gluc} is the plasma glucose concentration and BUN is blood urea nitrogen concentration, both in mg/dL. If there is a suspicion that an unmeasured, osmotically effective solute may be implicated (e.g., mannitol or glycerol), the P_{osm} should be measured directly.

Isotonic hyponatremia (also known as *factitious hyponatremia* or *pseudohyponatremia*) is a laboratory artifact seen with analytic techniques that measure the mass of sodium per unit volume of plasma sampled.¹⁸⁰ It is seen in the presence of marked hypertriglyceridemia or paraproteinemia, when the measurement method involves a predilution step. Direct potentiometry (which uses an ion-selective electrode in undiluted plasma) avoids this problem.¹⁸⁰

Hypertonic hyponatremia results from the presence in ECF of abnormal amounts of osmotically effective solutes other than sodium (e.g., glucose, mannitol, or glycerol). The osmotic pressure exerted by the nonsodium solute leads to redistribution of water from the intracellular to the ECF compartment, resulting in cellular dehydration and hyponatremia. The hyponatremia is real (not *pseudo*), but it is accompanied by *hypertonicity* and a *decrease* in cellular volume.

Hypotonic hyponatremia is almost always caused by an inability of the kidney to excrete sufficient electrolyte-free water to match water intake. This may occur either because the normal diluting capacity of the kidney is overwhelmed by excessive water intake or because the diluting capacity of the kidney is impaired. These alternatives usually can be distinguished by measuring the urine osmolality. A urine osmolality less than 100 mOsm/kg in a patient with hypotonic hyponatremia points to excessive water intake as the cause (Fig. 57.5). It is a prodigious feat for an individual eating a normal diet to overwhelm the normal diluting capacity of the kidney. Estimates are that one can ingest (and excrete) about 20 L of water a day without affecting the plasma osmolality appreciably.¹⁷³ Thus, patients who develop hyponatremia from so-called *psychogenic* or *primary polydipsia*—usually patients with obsessive-compulsive disorder or psychosis—typically have concurrent urinary diluting defects, either in association with the underlying mental illness or perhaps as a side effect of psychotropic or anticonvulsant medications.¹⁸¹

Not all patients with hypotonic hyponatremia and a dilute urine have primary polydipsia. The patient may be ingesting a diet so deficient in protein and salt that he excretes very little solute in the urine. In that situation (called *beer potomania* for obvious reasons,¹⁸² although the syndrome has been seen in other patients with very low daily solute intake¹⁸³) the low daily solute excretion limits the total amount of water that can be eliminated even with a maximally dilute urine (i.e., maximum urine volume = solute excretion ÷ minimum U_{osm}). This might reduce the maximum water excretion to only 3 to 4 L/day, a quantity easily exceeded by an enthusiastic beer drinker.

A urine osmolality above 100 mOsm/kg in the face of hypotonic hyponatremia signifies impaired urinary diluting

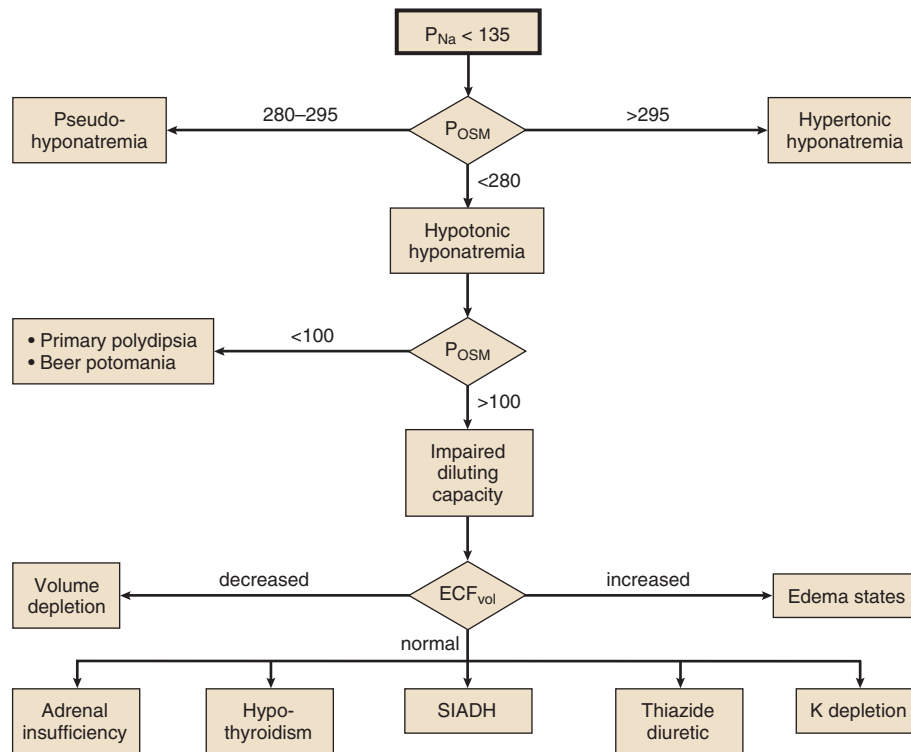

Figure 57.5 Diagnostic evaluation of hyponatremia. ECF_{vol}, extracellular fluid volume status; P_{Na}, plasma sodium concentration; P_{osm}, plasma osmolality (mOsm/kg); SIADH, syndrome of inappropriate antidiuretic hormone secretion; U_{osm}, urine osmolality (mOsm/kg).

capacity. The concentrated urine usually reflects a high circulating AVP level. Because circulating AVP is affected by systemic hemodynamics as well as osmolality, assessment of the patient's ECF volume status and hemodynamics is crucial at this juncture. Hypotonic hyponatremia may be associated with normal, decreased, or increased extracellular volume.

Euvolemic Hyponatremia

Patients with pure water excess appear clinically euvolemic because excess water distributes throughout the total body water space; only one third of total body water is extracellular (and only one twelfth is intravascular). The only evidence of the slight intravascular volume expansion is low BUN and plasma uric acid concentration.¹⁸⁴ The paradigm of euvolemic hyponatremia with a concentrated urine is the syndrome of inappropriate antidiuretic hormone secretion (SIADH). It is characterized by elevated circulating AVP (ADH) levels that are inappropriate to vasopressin's two physiologic stimuli (i.e., osmotic or hemodynamic).¹⁸⁵ Hypotonic hyponatremia in patients with SIADH develops to the extent that water ingestion exceeds water eliminated by insensible, GI, and renal routes. Because the normal response to extracellular hypotonicity is the elaboration of maximally dilute urine (urine osmolality < 100 mOsm/kg), the urine need only be inappropriately concentrated (i.e., >100 mOsm/kg) to be compatible with a diagnosis of SIADH.

Because hypothyroidism¹⁸⁶ and glucocorticoid insufficiency¹⁸⁷ may impair urinary dilution, patients in whom a diagnosis of SIADH is entertained should undergo

appropriate tests of thyroid and adrenocortical function. (see Chapter 59.)

Once a diagnosis of SIADH is made, its cause must be established, because the cause may have important implications in its own right and may be easily remediable. [Box 57.8](#) lists important causes of SIADH. They fall into five major categories: intracranial abnormalities, intrathoracic abnormalities, tumors, drugs, and idiopathic. An important variant of SIADH is the *reset osmostat syndrome*,¹⁸⁸ in which vasopressin levels are regulated normally by tonicity but around a lower "set point" than normal. This syndrome is seen most often in patients who are severely debilitated (e.g., malnutrition, metastatic cancer, advanced tuberculosis) and may account for up to one third of cases of SIADH. The diagnosis of reset osmostat syndrome has important therapeutic implications, as will be discussed later.

Hypovolemic Hyponatremia

The urinary diluting impairment in hypovolemia is mediated both by decreased delivery of fluid to the diluting segments of the nephron and by hemodynamically stimulated vasopressin release. Thus, the volume-contracted patient cannot excrete electrolyte-free water normally, and even in the face of modest water ingestion readily may become hyponatremic.

The cause of the volume contraction usually is obvious (e.g., hemorrhage, vomiting, diarrhea, diuretics). When it is not, the urine sodium concentration can be helpful in distinguishing between renal and extrarenal solute losses. Renal losses (e.g., as a result of diuretic medications) are usually reflected by sodium wasting, and extrarenal losses

are usually accompanied by sodium conservation (urine sodium concentration < 10 mM). Exceptions occur in the recovery phase after diuretic therapy and in metabolic alkalosis due to vomiting. In the latter situation, the urine chloride concentration tends to be very low and is the best indicator of extracellular volume depletion.^{189,190}

Cerebral salt wasting may be responsible for hypovolemic hyponatremia in patients with intracranial pathology (e.g., tumors, hemorrhage). The pathogenesis of the urinary salt wasting is incompletely understood. The mechanism of hyponatremia in this setting is similar to that of other hypovolemic states. As a hyponatremic syndrome in patients with central nervous system disease, cerebral salt wasting is often difficult to distinguish from SIADH because urinary sodium excretion tends to be high. Particularly confusing in patients with cerebral salt wasting is the finding of *hypouricemia*, which is thought to reflect impaired solute reabsorption in the proximal tubule.¹⁹¹ The key features that distinguish cerebral salt wasting from SIADH are volume depletion and urinary sodium excretion inappropriate to the patient's volume status.¹⁹¹

The hyponatremia associated with *diuretic treatment* is multifactorial in origin. Insofar as diuretics produce overt volume depletion, they can cause hyponatremia by the mechanisms discussed previously. Thiazides have been associated with the development of acute severe, symptomatic hyponatremia, particularly in small, elderly women, in the absence of overt signs of volume depletion.¹⁹² The cause of this often precipitous syndrome remains uncertain.¹⁹³

Hypervolemic Hyponatremia

Hypervolemic hyponatremia generally is seen in patients who cannot excrete sodium normally because they have either severe renal failure or one of the pathologic edema-forming states (e.g., congestive heart failure, hepatic cirrhosis, nephrotic syndrome). Patients with advanced chronic kidney disease are predisposed to hyponatremia.¹⁹⁴ Acute oliguric renal failure or end-stage (dialysis-dependent) renal failure will be accompanied by hyponatremia to the extent that water intake exceeds insensible and GI water elimination (see Chapter 55).

Hyponatremia is seen in over 20% of patients presenting with decompensated congestive heart failure and over 30% of patients admitted to hospital with complications of hepatic cirrhosis.¹⁹⁵ The hormonal milieu of such patients is typical of intravascular volume depletion, even though the absolute intravascular volume typically is increased. Thus, these disorders are said to be characterized by *reduced effective circulating volume*.¹⁹⁶ Because of the perceived intravascular volume depletion, renal diluting ability is compromised for reasons similar to those in hypovolemic hyponatremia.

Hyponatremia in Endurance-Sports Athletes

The incidence of hyponatremia, with serum sodium less than 135 mmol/L, is approximately 15% in marathon and triathlon athletes; 0.6% of runners develop severe hyponatremia with serum sodium levels less than 120 mEq/L.¹⁹⁵ The three major risk factors associated with hyponatremia in this setting includes body mass index (BMI) less than 20, racing time more than 4 hours, and weight gain related to excessive fluid intake during the race. Fluid overload is the most important factor in the development of hyponatremia for runners.¹⁹⁵

MANAGEMENT AND COMPLICATIONS

Hyponatremia per se requires treatment only when it is associated with hypotonicity. Hypertonic hyponatremia responds to the treatment of the underlying disorder,

most commonly a hyperosmolar hyperglycemic state (see Chapter 58).

The therapy of hypotonic hyponatremia must be tailored to (1) the patient's signs and symptoms, and (2) the duration of the disorder.¹⁷⁵ Severe hyponatremia (plasma sodium concentration < 115 mmol/L) can be life threatening, especially if it develops rapidly.^{177,197} The therapy of symptomatic hyponatremia, irrespective of cause, is directed at raising ECF tonicity to shift water out of the intracellular space, thereby ameliorating cerebral edema. The rate of correction, however, must be carefully regulated. Overly rapid correction, particularly in patients with chronic hyponatremia, in whom cell volume adaptations may be complete, can produce *osmotic demyelination syndrome*.^{198,199} Osmotic demyelination syndrome is associated with a variety of sometimes irreversible neurologic deficits (e.g., dysarthria, dysphagia, behavioral disturbances, ataxia, quadriplegia, coma), which typically develop 3 to 10 days after treatment.²⁰⁰ Additional risk factors for osmotic demyelination include hypokalemia, malnutrition, alcoholism, advanced age, female gender, and the postoperative state, particularly after orthotopic liver transplantation.²⁰¹⁻²⁰³

For patients with chronic hyponatremia (>48 hours duration) or hyponatremia of unknown duration, the plasma sodium concentration should be raised by a maximum of 0.5 mmol/L/hour, 8 to 10 mmol/L in the first 24 hours¹⁹⁹ and 20 mmol/L over the first 48 hours. Care should be taken to avoid *overcorrecting* the plasma sodium concentration.^{187,200} In grave situations (plasma sodium concentration < 105 mmol/L or in the presence of seizure or coma), initial therapy can be more aggressive (targeting a change in the plasma sodium concentration of 1 to 2 mmol/L/hour for the first few hours), but the recommended daily target should not be exceeded.^{187,200}

Correction of severe symptomatic hypotonic hyponatremia, regardless of cause, should be accomplished with hypertonic (3%) saline (sodium concentration 513 mmol/L). The volume of 3% saline required can be estimated by the following formula:

$$\begin{aligned} \text{volume of 3\% saline (L/24 hours)} \\ = \text{target change } P_{\text{Na}} \text{ (mmol/L/24 hours)} \\ \times \text{TBW (L)} \div 513 \end{aligned}$$

For example, in a 70-kg man with a plasma sodium concentration of 105 mmol/L and total body water (TBW) of 42 L (60% of body weight), the amount of sodium needed to raise the plasma sodium concentration by 10 mmol/L is 10×42 , or 420 mmol. Therefore, $420 \div 513$ or 0.82 L of 3% saline would be required in the first 24 hours, or 34 mL/hour. It is important to recognize that the calculation provides only a very rough guideline. The plasma sodium concentration must be monitored frequently during treatment to adjust the rate of correction. If the rate of correction begins to exceed the target rate, the hypertonic saline infusion should be stopped; rarely, it may be necessary to administer water (enterally or intravenously) or even desmopressin²⁰⁴ in order to prevent overly rapid correction or overcorrection. Rapid extracellular volume expansion with hypertonic saline may precipitate pulmonary edema, particularly in patients with underlying heart disease. Thus, patients receiving 3% saline should be assessed frequently for evidence of volume overload. One may administer a

loop diuretic if necessary, recognizing that this will enhance electrolyte-free water clearance and accelerate the correction. Rarely, administration of isotonic (normal) saline to patients with SIADH paradoxically may *lower* the plasma sodium concentration if the urine osmolality remains high—a process that has been called *desalination*.²⁰⁵

The treatment of chronic asymptomatic hypotonicity should be directed at correcting the pathophysiologic mechanisms involved in generating the hypotonic state. Because euvoletic hyponatremia represents pure water excess, treatment depends on restricting water intake to less than the daily water output. Patients with SIADH excrete little or no electrolyte-free water in the urine. Therefore, if water intake is limited to less than the amount of insensible water losses (approximately 10 mL/kg/day), the plasma sodium concentration will slowly rise. Patients with the reset osmostat variant of SIADH characteristically do not develop progressive hypotonicity, and therapy is rarely required.

If the cause of SIADH cannot be corrected and if water restriction is poorly tolerated or ineffective, a specific vasopressin (V_2) receptor antagonist (VRA) can be used.²⁰⁶ Conivaptan (parenteral) and tolvaptan (oral) were the first VRAs to be approved by the U.S. Food and Drug Administration for clinical use. These agents have changed the management of patients with SIADH.²⁰⁷ Tolvaptan reliably increases P_{Na} concentration, but hyponatremia recurs within 1 week after the medication is discontinued.²⁰⁸ For patients admitted with hyponatremia related to decompensated congestive heart failure, tolvaptan along with diuretic therapy improves most signs and symptoms of heart failure within 1 week,²⁰⁹ although no effect on 24-month mortality rate or heart failure morbidity has been demonstrated.²¹⁰ Before the introduction of VRAs, demeclocycline (a tetracycline antibiotic that increases electrolyte-free water excretion by inhibiting vasopressin-mediated water reabsorption in the collecting duct) was commonly used to treat patients with SIADH. Demeclocycline is contraindicated in patients with renal disease, hepatic cirrhosis, or congestive heart failure because drug-related renal insufficiency has been described in these situations.²⁰⁶ Neither VRAs nor demeclocycline are indicated for the treatment of acute, severe hyponatremia.

Therapy of hypovolemic hyponatremia should be directed at restoring intravascular volume with intravenous isotonic saline while identifying and correcting the cause of the excessive solute loss. Volume repletion readily elicits a water diuresis by increasing the delivery of fluid to the renal diluting segments and suppressing vasopressin release. As with all categories of hypotonic hyponatremia, the rate of correction must be carefully controlled.

The treatment of diuretic-induced hyponatremia is straightforward: Withdrawing the offending drug, liberalizing salt intake, and replenishing body potassium stores usually correct the disorder. Severe symptomatic hyponatremia in this setting should be treated with hypertonic saline as detailed earlier. Patients must be watched carefully after correction of the hyponatremia because relapse may occur for up to a week.¹⁹³

Resolution of the hyponatremia associated with any of the pathologic edematous disorders ultimately depends on effective treatment of the underlying disease. Regardless of the specific therapy of the underlying disorder, the mainstay

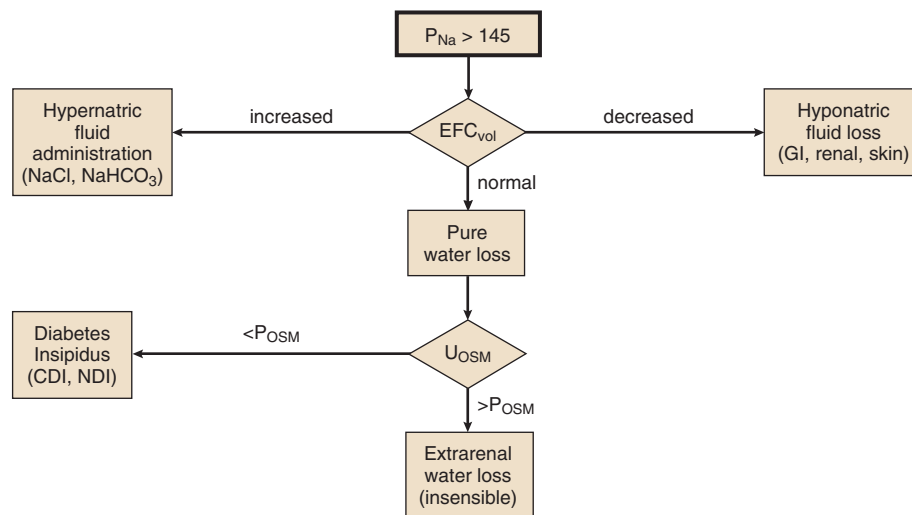

Figure 57.6 Diagnostic evaluation of hypernatremia. See Figure 57.3 legend for abbreviations. CDI, central diabetes insipidus; GI, gastrointestinal; NDI, nephrogenic diabetes insipidus.

of therapy for the hyponatremic edematous patient remains salt and water restriction. Diuretics are often a double-edged sword in the hyponatremic edematous patient: They may be needed to treat pulmonary vascular congestion, peripheral edema, and ascites but if used to excess can produce further decrements in effective arterial blood volume and exacerbate water retention. Strategies directed at increasing effective arterial blood volume (e.g., afterload reduction with angiotensin-converting enzyme inhibitors^{211,212}) have had some success in increasing electrolyte-free water excretion and ameliorating hyponatremia in patients with congestive heart failure. VRAs are likely to facilitate treatment of hypervolemic hyponatremia (see earlier).²⁰⁷

HYPERNATREMIA

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

Hypernatremia is common in critically ill patients, being present on admission in about 9% of patients and developing during the course of the ICU stay in another 6%.²¹³ It is associated with a significantly higher mortality rate than is seen in patients without hypernatremia.²¹³

Sustained hypernatremia develops in patients whose water output exceeds their input. Water ingestion can defend against the development of hypernatremia even when water losses are prodigious. For that reason, hypernatremia upon presentation to the hospital occurs most commonly in patients who are incapacitated: those who have impaired thirst sensation, who cannot access water, or who cannot express their need for water (e.g., infants and patients with neurologic impairments). Similar predispositions prevail among critically ill patients. Thus, the development of hypernatremia in hospitalized patients is considered to be iatrogenic, reflecting an incomplete understanding of the factors that lead to hypernatremia.²¹³ The increased mortality rate seen in patients with hypernatremia probably is due to their underlying vulnerabilities rather than an effect of the hypernatremia itself.²¹⁴

The clinical manifestations of hypernatremia are proportional to the magnitude and rate of rise of the plasma

sodium concentration and are attributable to intracellular volume contraction. To counteract cellular volume contraction, cells begin to adapt within minutes by allowing the influx of electrolytes, thus mitigating cell shrinkage. When hypernatremia lasts more than a few hours, brain cells generate new *organic osmolytes*. This leads to further water movement back into brain cells, restoring cell volume nearly to normal after about 3 days.²¹⁵ Thus, chronic progressive hypernatremia is associated with fewer and milder symptoms than acute severe hypernatremia. Most often, patients with longstanding hypernatremia present with weakness, lethargy, and confusion. Seizure and coma may supervene. Acute severe hypernatremia in infants and small children is associated with intracranial bleeding,²¹⁶ presumably caused by brain shrinkage and traction on the penetrating vessels. There is some controversy, however, as to whether the hypernatremia in that situation is the cause or the effect of the intracranial hemorrhage.²¹⁷

DIFFERENTIAL DIAGNOSIS

The plasma sodium concentration reflects the ratio of body sodium content to total body water. Thus, hypernatremia (plasma sodium concentration > 145 mmol/L) can result from loss of pure water alone, loss of *hyponatric** fluid, or a gain of sodium or *hypernatric* fluid. It is important to distinguish among these paths to hypernatremia because they have diagnostic and therapeutic implications (Fig. 57.6).

Euvolemic Hypernatremia

Hypernatremic patients who appear euvolemic most likely have pure water loss as an explanation for their hypernatremia. This is because the water is lost from all body compartments proportionately; only one twelfth of the water loss is intravascular. For example, a 60-kg woman with a 3 L pure

**Hyponatric* and *hypernatric* are used here to refer to a fluid with a sodium concentration less than (or greater than) that of plasma.

water loss would experience an intravascular loss of only 250 mL (clinically imperceptible) but would develop a plasma sodium concentration of 155 mmol/L.* Pure water can be lost either through the skin and respiratory tract (so-called *insensible* losses) or in urine.

Insensible losses amount to about 10 mL/kg/day under normal environmental conditions in an afebrile individual with a normal respiratory rate. A hot environment, fever, or rapid respiratory rate may double that rate.¹⁷³ Note that a patient on a mechanical ventilator using humidified gas will lose no water through the respiratory tract.

The loss of large amounts of dilute, electrolyte-free water in the urine is typical of *diabetes insipidus* (DI). DI may be central (CDI) or nephrogenic (NDI) depending on whether the defect is in vasopressin release from the posterior pituitary or in renal response to circulating vasopressin, respectively. The causes of DI are shown in Box 57.9. Most cases of CDI, especially those following trauma or intracranial surgery, are self-limited, lasting 3 to 5 days. Of special interest to intensivists is a classic triphasic syndrome that may be seen following severe head trauma:

1. Initially, there is abrupt cessation of vasopressin release from the posterior pituitary, accompanied by polyuria.
2. About a week later, an antidiuretic phase ensues, characterized by urinary concentration and water retention with a tendency toward hyponatremia, lasting 5 to 6 days. This appears to result from the release of stored vasopressin from the degenerating hypothalamic neurons.
3. Persistent CDI recurs when the vasopressin stores are depleted.²¹⁸

Regardless of the cause, patients with DI of either type usually have a plasma sodium concentration within the normal range because their water ingestion matches their urinary water output. They develop hypernatremia only with water deprivation due to mental or physical incapacity or neglect. An awareness of the causes of DI, a careful history, and familiarity with the differential diagnosis of polyuria will prevent hypernatremia in these circumstances.

Hypovolemic Hypernatremia

The loss of salt and water, with the water loss greater than the sodium loss, will lead to hypernatremia and volume depletion, manifested by orthostatic or persistent hypotension and tachycardia and evidence of organ underperfusion (e.g., acute renal failure, lactic acidosis). For example, if the 60-kg woman whose plasma sodium concentration rose to 155 mmol/L (see earlier) had lost the equivalent of half-isotonic saline instead of pure water, her intravascular volume would have contracted by 750 mL, enough to cause at least orthostatic hypotension and tachycardia.

A common cause of hypovolemic hypernatremia is the loss of GI fluids.²¹⁹ Most GI fluids have an electrolyte concentration below that of plasma: The concentration of

sodium plus potassium in stool is roughly constant at 110 to 120 mmol/L over a wide range of stool volume.¹²⁵ Gastric fluid has an even lower electrolyte concentration: about 40 to 50 mmol/L total cation concentration.²²⁰ Diuresis, either osmotic (glucose-, mannitol-, or urea-induced) or medication-induced, causes the loss of urine with an electrolyte concentration less than that of plasma, leading to volume contraction and hypernatremia. The loss of sweat, which contains some sodium, can cause hypovolemic hypernatremia in individuals who exercise vigorously in a hot environment. If the cause of the fluid loss is not apparent from the history or the physical examination, a urinary chloride concentration less than 10 mmol/L in the face of hypovolemic hypernatremia suggests that the electrolyte loss is extrarenal (cutaneous or GI).

*The expected change in the serum sodium concentration is calculated as follows: [initial total body water volume] × [serum sodium concentration initial] ÷ [final total body water volume]; 30 L × 140 mmol/L ÷ 27 L = 155 mmol/L.

Hypervolemic Hyponatremia

Hypervolemic hyponatremia is relatively uncommon. It results most often from the administration of hypertonic sodium salts to patients without free access to water.²¹⁹ Patients show signs of extracellular volume expansion (e.g., hypertension, edema, congestive heart failure, and pulmonary edema). In infants, this syndrome has been caused by erroneous preparation of dietary formula using salt instead of sugar; in adult outpatients, it may be caused by ingestion of a concentrated salt solution, usually for its emetic effect.²²¹ The risk of death is substantial and seems to be proportional to the plasma sodium concentration.²²¹

In hospitalized adults, hypervolemic hyponatremia is most often iatrogenic, caused by intravenous administration of undiluted sodium bicarbonate (formulated at 1 mEq/mL or 1000 mmol/L) or sodium chloride (3% [513 mmol/L] or 23.5% [4019 mmol/L]). Not all hypervolemic hyponatremia results from the administration of hypertonic fluids. It may be seen in a volume-expanded patient who then loses hypotonic fluid.²²²

TREATMENT

The initial treatment of the hyponatremic patient depends on his or her volume status. For patients with pure water losses (euvoletic), therapy has two goals: (1) reduction or replacement of ongoing water losses, and (2) replacement of the existing water deficit.

If the water losses are urinary (see Fig. 57.6) and due to CDI, ADH should be administered. Several formulations are available (Table 57.3). In the acute (postsurgical or post-traumatic) setting, L-arginine vasopressin may be used either subcutaneously or intravenously, although the latter route may be associated with hypertension and coronary spasm and should therefore be used with extreme caution.²²³ The advantage of vasopressin in this setting is its short half-life, which allows the physician to repeatedly assess the need for continued hormone replacement, especially when the disorder may be self-limited. Desmopressin (DDAVP) is a synthetic analog of vasopressin that has no vasoconstrictor properties, thus avoiding the risks of hypertension and myocardial ischemia. The treatment of the urinary water losses associated with NDI are best treated with thiazide diuretics with or without COX inhibitors. Because most of these

agents are orally administered, treatment of NDI in the critically ill patient often consists of urinary water replacement until he or she is able to take medications by mouth.

The current body water deficit can be estimated by the following formula:

$$\text{Water deficit (liters)} = \text{TBW} (1 - [140 \div \text{current } P_{Na}])$$

where TBW is total body water in liters (estimated as about $0.5 \times \text{lean body weight [kg]}$ in women and $0.6 \times \text{lean body weight in men}$). For example, a 60-kg woman presenting with a plasma sodium concentration of 160 mmol/L is estimated to have a total body water deficit of 30 ($1 - 0.875$), or 3.75 L. This formula provides only a rough estimate of the water deficit.

The rate of water replacement should be proportional to the rapidity with which the hyponatremia developed.²¹⁵ Thus, if the hyponatremia had developed over only a few hours (such as in postsurgical or posttraumatic DI), it can be corrected just as quickly. On the other hand, hyponatremia of more than a day's duration, or of unknown duration, must be corrected slowly in order to avoid cerebral edema. In general, one should aim to correct half the water deficit in the first 24 hours and the remainder over the next 24 to 48 hours.

Water is best administered enterally, as tap water. If that route is unavailable, 5% dextrose in water (D₅W) may be used, with the understanding that the capacity to metabolize glucose is limited to about 15 g/hour in a critically ill adult.²²⁴ Thus, even in nondiabetic patients, the administration of more than 300 mL/hour of D₅W is likely to result in hyperglycemia, which may be relatively resistant to insulin administration. Hyperglycemia will exacerbate urinary water losses by causing an osmotic diuresis. Half-normal (0.45%) saline may be a good alternative, as long as one recognizes that only half the administered volume is electrolyte-free water and that the sodium load may cause unwanted volume expansion.

Regardless of the degree of hyponatremia, normal (.9%) saline should be given intravenously to patients who present with obvious volume depletion, manifested by hypotension, tachycardia, and evidence of impaired tissue perfusion. This is consistent with the first principles of emergency and critical care, prioritizing the adequacy of the circulation. Only

Table 57.3 Pharmacologic Treatment of Central Diabetes Insipidus

Agent	Total Daily Dose	Frequency of Administration	Time to Onset (h)	Duration of Action (h)	Comments
Arginine vasopressin, 20 units/mL	5-10 units subcutaneous	q2-4h	1-2	2-6	Intravenous route may cause vasoconstriction and coronary spasm
Desmopressin acetate (DDAVP)					
10 µg/0.1 mL intranasal	10-40 µg intranasal	Daily or bid	1-2	8-12	
4 µg/mL injection	2-4 µg IV or subcutaneous	Daily or bid	1-2	8-12

after the extracellular volume deficits have been largely corrected may the physician direct his or her attention to the total body water deficit (see earlier).

Patients with hypervolemic hyponatremia need reduction in their extracellular and intravascular volume before their water deficit can be corrected. Failure to do so will exacerbate the volume overload. For patients with adequate renal function, this may be accomplished with the use of diuretic drugs. Loop diuretics tend to cause the excretion of an isotonic urine. Replacement of that urine volume with pure water will allow correction of the hypervolemia and the hyponatremia simultaneously.

Because of the imprecision of the estimation formulas and the failure of the foregoing analysis to take account of other fluids and electrolytes both administered and lost, it is crucial that the plasma electrolytes be monitored frequently during the correction of hyponatremia, especially in view of the dire consequences of overly rapid correction.

CALCIUM HOMEOSTASIS

Calcium (Ca) is required for bone mineralization, muscle contraction, nerve conduction, and blood coagulation. It is required for cell division, hormone secretion, phagocytosis, chemotaxis, and activation of numerous intracellular second messengers.²²⁵ Calcium is also responsible for activation of calcium-dependent phospholipases and proteases, generation of free radicals, release of cytokines, and inhibition of adenosine triphosphate (ATP) production in the face of ischemic injury. Thus calcium plays a central role in physiologic as well as pathologic conditions.²²⁶

NORMAL CALCIUM PHYSIOLOGY

Calcium is the most abundant cation in the body. The total body calcium content of an average adult is approximately 1 kg, 99% of which is found in bones and teeth, with only 1% in plasma and soft tissues.²²⁷ Calcium homeostasis is achieved with the cooperation of several organs, including the skeleton, the gut, and the kidney, under the influence of several hormones, mainly vitamin D, parathyroid hormone (PTH), and calcitonin.

CALCIUM INTAKE AND ABSORPTION

The typical daily dietary intake of calcium for an average adult in North America is 800 to 1000 mg. The main dietary source of calcium is milk and other dairy products; it is also available in the form of fortified food and calcium-containing supplements. Approximately 20% of dietary calcium is absorbed by intestine. Intestinal absorptive capacity increases with calcium deprivation and under certain physiologic conditions such as growth spurt in children, pregnancy, and lactation.²²⁸ Intestinal absorption occurs via both passive paracellular and active transcellular pathways. Vitamin D increases the active transport of calcium across the intestinal membranes.²²⁷

RENAL HANDLING OF CALCIUM

The filtered load of calcium (the product of glomerular filtration rate and the plasma concentration of

ultrafilterable calcium) is about 10 g/day. Calcium balance is maintained when the kidneys excrete about 200 mg/day (the intestinal absorptive load). Thus, the fractional excretion of calcium is only about 2%.^{227,228} Of the 98% of filtered calcium reabsorbed along the nephron, 60% is reabsorbed in the proximal tubule. Approximately 15% of the filtered calcium is reabsorbed in the thick ascending limb of loop of Henle (TAL). The reabsorption of calcium in TAL is mostly passive and proportional to the lumen-positive voltage generated by the furosemide-inhibitable Na-K-Cl cotransporter (NKCC2) channel and potassium recycling via renal outer medullary potassium (ROMK) channels. There is also some active transcellular transport, which is under the influence of PTH and calcitonin.^{227,228} In the distal tubule, approximately 10% to 15% of filtered calcium is reabsorbed via active transcellular pathways. The apical membranes of distal convoluted tubules (DCT) and connecting tubules (CNT) contain highly selective epithelial calcium channels (TRPV-5)^{227,228} that facilitate calcium entry into the cells. PTH increases the density and open probability of TRPV-5 channels.²²⁹

Volume expansion, hypercalcemia, acute and chronic acidosis, and loop diuretics reduce the renal calcium reabsorption and result in hypercalciuria. Conversely, hypocalcemia, alkalosis, PTH, calcitriol, and thiazide diuretics enhance renal calcium reabsorption and cause hypocalciuria.

REGULATION OF PLASMA CALCIUM

Normal plasma calcium concentration is 8.8 to 10.4 mg/dL. In plasma, calcium exists in two forms: protein-bound and *ultrafilterable* (permeant across the glomerular filtration barrier). Approximately 40% of plasma calcium is bound to plasma proteins (predominantly albumin), cannot cross the biologic membranes, and is thus physiologically inert. The ultrafilterable portion of plasma calcium makes up the remaining 60% of plasma calcium and consists of calcium complexed with various anions like citrate, phosphate, and lactate (about 10%) and free, ionized calcium (Ca^{2+})—the biologically active form—accounting for about 50% of plasma levels.²³⁰

Plasma Ca^{2+} concentration is tightly regulated. Several factors play an important role in maintaining plasma Ca^{2+} concentration within a narrow range (about 4.4-5.2 mg/dL or 1.1-1.3 mmol/L). The principal regulators are PTH, vitamin D₃, and Ca^{2+} itself.

Ca^{2+} acts as a ligand for calcium-sensing receptors (CaSR) present on the chief cells of the parathyroid glands. A rise in plasma Ca^{2+} concentration results in activation of CaSR, which in turn inhibits PTH secretion. Conversely, a fall in Ca^{2+} concentration inhibits CaSR, increasing PTH secretion. PTH mobilizes the calcium from bone stores, stimulates renal calcium reabsorption, and increases the conversion of 25(OH)D₃ to 1,25(OH)₂D₃, the most active form of vitamin D₃. Activated vitamin D₃ increases intestinal calcium absorption. All these systems work in concert to keep the Ca^{2+} levels within physiologic levels.²²⁵

PLASMA CALCIUM MEASUREMENT

Ca^{2+} is the physiologically important moiety, yet total calcium is most often measured in clinical laboratories. Under normal circumstances, there is a fairly constant relationship

between total and ionized calcium (see earlier), but in critically ill patients, this relationship may be disturbed such that total calcium no longer provides a reliable index of the physiologically important calcium concentration. The two major factors affecting the ratio of ionized to total calcium are acid-base status and plasma protein concentration.

Acidemia causes displacement of calcium ions from albumin by protons and results in a relative increase in Ca^{2+} . Conversely, alkalemia increases calcium binding to albumin, causing a relative fall in Ca^{2+} levels while total plasma calcium concentration remains unchanged.^{225,227}

Changes in the concentration of plasma protein, especially albumin, result in alterations in total calcium concentration: Hypoalbuminemia, common in critically ill patients, causes a reduction in total calcium concentration; hyperalbuminemia (e.g., in states of severe volume contraction) tends to cause an increase in total plasma Ca. Numerous formulas have been proposed to adjust the total calcium concentration for changes in plasma albumin concentration.²³¹ The most commonly used formula is based on the observation that each gram of albumin binds about 0.8 mg calcium at physiologic pH:

$$\text{Ca}_{\text{corrected}} = \text{Ca}_{\text{observed}} + (0.8 \cdot [4.0 - \text{albumin}])$$

Unfortunately, the corrected calcium correlates very poorly with Ca^{2+} in various critically ill populations, typically with a very low sensitivity for diagnosis of true hypocalcemia.²³¹⁻²³³

The reasons for this discrepancy are manifold, including concurrent acid-base disorders, high circulating concentrations of free fatty acids,²³⁴ and infusions of heparin, citrate, and bicarbonate.²³³ Therefore, in critically ill patients, direct measurement of Ca^{2+} is recommended for assessing physiologic calcium concentration.

HYPOCALCEMIA

EPIDEMIOLOGY

Hypocalcemia is extremely common in critically ill patients. The prevalence of ionized hypocalcemia is reported to be 60% to 85% among medical, surgical, and trauma ICU patients.²³⁵⁻²³⁸ Risk factors for the development of hypocalcemia in critically ill patients include advanced age, sepsis, acute renal failure, multiple blood transfusion, malnutrition, magnesium deficiency, severe shock, and colloid volume resuscitation.^{238,239} Mortality rate is higher in hypocalcemic patients^{236,240,241} but does not appear to be independently associated with hypocalcemia.^{237,238}

CAUSES OF HYPOCALCEMIA

Causes of hypocalcemia are shown in [Box 57.10](#). Hypocalcemia may be caused by disorders involving the hormonal regulators of calcium homeostasis, PTH, and vitamin D; redistribution of calcium; drugs; and miscellaneous influences. We will discuss causes of particular relevance to the critical care setting.

Hypoparathyroidism

Parathyroidectomy, for hyperparathyroidism or “incidentally” with thyroidectomy, may cause postoperative hypocalcemia. Risk factors for developing hypocalcemia include subtotal parathyroidectomy and simultaneous thyroidectomy. Profound, long-lasting hypocalcemia may develop as

Acute renal failure

part of the “hungry bone” syndrome, in which calcium is sequestered into the rapidly remineralizing bone.²⁴² Hypomagnesemia may contribute to the hypocalcemia (see discussion under “[Magnesium Homeostasis](#)”).

Vitamin D Deficiency

Vitamin D deficiency is common in elderly, institutionalized patients due to poor dietary intake and inadequate sunlight exposure. Diseases involving liver and small intestine may result in poor absorption of vitamin D. For conversion to its most active form, vitamin D requires hydroxylation in liver and kidney. Frequently, critically ill patients suffer from liver and kidney dysfunction, which results in impaired vitamin D synthesis and predisposes to hypocalcemia.²²⁶ Vitamin D deficiency (level <20 ng/dL) upon admission to a medical ICU has been associated with increased mortality rate.²⁴³ Whether vitamin D supplementation to critically ill patients will reduce mortality rate remains to be determined.

Redistribution

Citrate is useful as a preservative and anticoagulant for blood components precisely because it chelates calcium and thereby inhibits the coagulation cascade. The calcium citrate complex is then metabolized in liver, where citrate is converted into bicarbonate, and ionized calcium is released into the circulation. Massive blood transfusion may result in ionized hypocalcemia due to chelation of calcium by citrate. However, hypocalcemia is transient in patients with normal liver function and ionized calcium levels return to normal levels within 15 minutes of transfusion.²⁴⁴ Citrate also may be used for anticoagulation of the dialysis circuit for continuous renal replacement therapy (CVVHD and variants). Under those conditions, calcium typically is infused through a central venous line to prevent hypocalcemia. Inadequate calcium replacement or concomitant liver failure may result in clinically significant hypocalcemia. In the latter case, with citrate accumulation, the total calcium may be misleadingly normal, but the Ca^{2+} is low.^{245,246} Hypocalcemia is frequently reported with plasmapheresis where citrate is used for anticoagulation.²⁴⁷ Sodium *bicarbonate* to treat metabolic acidosis may cause hypocalcemia from calcium binding to albumin and formation of carbonate complexes. Similarly, abrupt alkalization from hemodialysis against a bicarbonate bath may precipitate symptomatic hypocalcemia.

Phosphate binds with calcium to form insoluble calcium phosphate complexes. Under normal physiologic conditions, calcium and phosphorus levels are tightly regulated, preventing significant complexation. Any condition that causes acute increase in phosphate levels, however, can cause complexation and resultant ionized hypocalcemia. Examples include endogenous phosphorus overload as in the tumor lysis syndrome⁷² and exogenous phosphorus overload from laxatives and cathartics.²⁴⁸⁻²⁵¹ Patients with impaired renal function are at particular risk.²⁴⁹ (See discussion under “[Phosphorus Homeostasis](#).”)

Hypocalcemia in *rhabdomyolysis* is multifactorial and involves calcium deposition in injured muscles, formation of calcium-phosphate complex due to hyperphosphatemia, and acute renal failure causing decreased synthesis of vitamin D.²⁵²

Ionized hypocalcemia is reported in up to 85% of patients suffering from acute severe *pancreatitis*.²⁵³ The cause of hypocalcemia in this setting is unclear. Calcium has been shown to accumulate in pancreas, liver, and skeletal muscle in an animal model of acute pancreatitis.²⁵⁴ Low²⁵⁵ and high^{256,257} levels of PTH have been reported. Experimental elevation in free fatty acids, both circulating²⁵⁸ (as might be seen in the hypertriglyceridemia of acute pancreatitis) and intra-peritoneal,²⁵⁹ have been associated with the hypocalcemia of acute pancreatitis. Finally, high circulating endotoxin levels may have a role.²⁵³

Drugs

Bisphosphonates are used for the treatment of osteoporosis and hypercalcemia. They act by impairing osteoclast function and reducing osteoclast numbers. Bisphosphonate-induced hypocalcemia has been reported in patients with renal failure, hypoparathyroidism, or vitamin D deficiency.²⁶⁰ Other drugs such as colchicine, plicamycin (formerly mithramycin), and calcitonin also decrease bone release of calcium.²²⁷

Sepsis/Systemic Inflammatory Response Syndrome

Hypocalcemia is common in patients suffering from sepsis or systemic inflammatory response syndrome.^{236,240} The cause probably is multifactorial.²⁶¹ Among the proposed mechanisms are calcium sequestration,^{262,263} an effect of inflammatory cytokines,²⁶⁴ calcitonin precursors,^{264,265} hypomagnesemia²⁶⁶ with inappropriate hypoparathyroidism,²⁶¹ and probable PTH resistance.^{264,267} Vitamin D deficiency, from malnutrition and inability to hydroxylate vitamin D due to coexisting liver and kidney dysfunction, also has been implicated.²⁶¹ The hypocalcemia may serve to protect vulnerable cells from the deleterious effects of calcium during sepsis. Indeed, calcium administration in this setting may be detrimental.²⁶¹

CLINICAL MANIFESTATIONS

Hypocalcemia affects predominantly the neuromuscular and cardiovascular systems. Neuromuscular manifestations include paraesthesias (perioral and acral), hyperactive reflexes, tetany (carpopedal spasm and other muscle spasm), and seizures.²²⁷ Laryngospasm and bronchospasm may supervene, leading to respiratory arrest.²²⁵ Tetany may be provoked by tapping over the facial nerve and noting ipsilateral facial muscle twitching (Chvostek sign) and transiently occluding the brachial artery with a tourniquet and noting carpal spasm (Trousseau sign), although neither of these signs is specific for hypocalcemia. Prolonged hypocalcemia lasting more than 36 hours has been associated with the development of critical illness polyneuropathy and myopathy.²⁶⁸ Psychiatric manifestations include anxiety, irritability, confusion, and psychosis.²²⁵

Cardiovascular findings include a prolonged QT interval and, in severe hypocalcemia, bradycardia, hypotension refractory to fluids and pressors, heart block, heart failure, and cardiac arrest.²²⁶

Symptoms and signs of hypocalcemia depend on the degree of depression of ionized calcium levels and the rate of decline.²²⁷ Mild hypocalcemia (ionized calcium > 3.2 mg/dL) usually is well tolerated.

DIAGNOSIS

When hypocalcemia is suspected in a critically ill patient, the diagnosis should be established by direct measurement of ionized calcium levels (see “[Plasma Calcium Measurement](#)”). If ionized hypocalcemia is confirmed, plasma magnesium and phosphorus should be measured. Further diagnostic evaluation derives from the differential diagnosis (see [Box 57.10](#)). Without PTH levels and vitamin D levels, the diagnosis of hypocalcemia remains obscure in the majority of critically ill patients.²³⁶

TREATMENT

Therapy of hypocalcemia depends on its severity. Hypocalcemia (ionized $\text{Ca} < 3.2$ mg/dL) accompanied by serious cardiovascular or neuromuscular signs should be treated urgently. Calcium gluconate (10% in 10 mL containing 90 mg elemental calcium) can be given over 5 to 10 minutes, followed by calcium gluconate infusion (500-1000 mg in 500 mL 5% dextrose) over 6 hours.²²⁷ Calcium chloride (10% in 10 mL containing 272 mg elemental calcium) contains more calcium and can rapidly increase plasma calcium

levels, however, it is more irritating to the veins and must be given by a central venous catheter. Patients with renal failure, hyperphosphatemia, and serious hypocalcemia may require dialysis.

Patients receiving intravenous calcium should have frequent measurement of the ionized calcium. They should be monitored for side effects of calcium administration including hypertension, skin flushing, nausea, vomiting, and chest pain.

Intravenous calcium should be reserved for patients who have severe hypocalcemia or who are incapable of taking calcium orally. Administration of intravenous calcium can cause complexing with phosphorus and ectopic calcification.

Critically ill patients with mild hypocalcemia ($iCa > 3.2$ mg/dL) tend to have few if any manifestations. Patients with longstanding or chronic hypocalcemia (e.g., due to vitamin D deficiency or hypoparathyroidism) should receive oral calcium supplementation. Calcium is available as carbonate, citrate, phosphate, and lactate salt. Calcium requirement varies between 1 and 4 g elemental calcium daily and must be given in divided doses. Vitamin D can be added with calcium to enhance intestinal absorption.

Several points in the management of hypocalcemia should be borne in mind. First, in cases of concomitant mild hypocalcemia with hyperphosphatemia (e.g., renal failure), the hyperphosphatemia should be corrected using phosphate binders because that alone will often lead to correction of the hypocalcemia. Second, magnesium deficits should be corrected because that may restore normal calcium physiology even without calcium supplementation (see discussion under “[Magnesium Homeostasis](#)”). Finally, concurrent severe metabolic acidosis should await correction of the hypocalcemia, because correction of the acidosis will be likely to worsen the ionized hypocalcemia and precipitate tetany.

HYPERCALCEMIA

Hypercalcemia has been reported in 15% to 30% of critically ill patients,^{267,269} and thus appears to be less common than hypocalcemia. It is more common in patients with higher severity of illness and in those with concurrent renal failure.^{267,269}

CAUSES OF HYPERCALCEMIA

Box 57.11 lists causes of hypercalcemia. About 90% of hypercalcemia in ambulatory and non-ICU patients is caused by only two entities: primary hyperparathyroidism and malignancy.²²⁵ The spectrum is a bit broader in critically ill patients.

Primary Hyperparathyroidism

Primary hyperparathyroidism is the most common cause of hypercalcemia, accounting for more than 50% of cases in ambulatory patients. Specific causes include benign adenoma (80-90%), hyperplasia (10-20%), and carcinoma (1%). Biochemical abnormalities include elevated circulating intact PTH, hypercalcemia, and hypophosphatemia.²²⁵

Malignancies

Hypercalcemia is rarely the presenting sign of a malignancy; most malignancies are advanced at the time hypercalcemia develops. About 40% of hypercalcemia in hospitalized patients has been associated with cancer.²⁷⁰ Almost 80% of malignancy-related hypercalcemia is secondary to the secretion of *parathyroid hormone-related peptide* (PTHrP) by the malignant cells.²⁷⁰ PTHrP is not detected by clinical laboratory assays for PTH. Numerous types of malignancies are associated with PTHrP-mediated hypercalcemia including breast,²⁷¹ renal cell, and ovarian carcinomas²²⁵ and hematologic malignancies.²⁷²

Increased production of $1,25-(OH)_2D_3$ by malignant cells is one of the causes of hypercalcemia in patients with lymphomas.^{273,274} Finally, osteolytic bone lesions from advanced cancers such as breast, lung, and multiple myeloma frequently result in hypercalcemia.²²⁵

Rhabdomyolysis

Rhabdomyolysis associated with acute renal failure commonly produces hypocalcemia during the initial phase (see “[Hypocalcemia](#)”). Approximately 30% of patients, mostly young men, develop hypercalcemia during resolution of the acute renal failure.²⁷⁵ Release from injured muscles of previously sequestered calcium appears to be the basis for the hypercalcemia.^{275,276} PTH is appropriately suppressed according to most^{277,278} but not all²⁷⁹ studies. Vitamin D levels may be elevated^{277,279} or suppressed,^{252,278} its contribution to the syndrome is unclear. Whatever the underlying mechanism, the hypercalcemia is usually mild and self-limited.²⁷⁵

Immobilization

Immobilization is associated with hypercalcemia due to increased bone resorption. Risk factors include duration of bed rest, spinal cord injury, multiple skeletal fractures, and underlying disorders leading to increased bone resorption (e.g., Paget disease, malignancy).^{280,281} Although

hypercalcemia is usually modest and completely reversible with activity, calcitonin and bisphosphonates can be used with success if treatment is required.²⁸⁰

Medications

A small percentage (5-10%) of patients treated with *lithium* develop hypercalcemia due to lithium-induced hyperparathyroidism.²²⁵ Hyperparathyroidism may or may not be reversible on discontinuation of therapy. *Thiazide diuretics* increase tubular reabsorption of calcium and are well known to cause modest hypercalcemia, which reverts back to normal upon discontinuation of therapy. More severe hypercalcemia should prompt an evaluation for occult hyperparathyroidism. *Vitamin A* may increase osteoclast-mediated bone resorption and cause hypercalcemia.

Milk-Alkali Syndrome

This syndrome comprises hypercalcemia (often extreme), metabolic alkalosis, and acute renal failure. It is seen in patients who ingest large quantities of alkaline calcium salts (e.g., calcium carbonate), often with vitamin D preparations.²⁸² Because of the increasing use of these medications to prevent or treat osteoporosis, the incidence of this syndrome, once considered rare, appears to be increasing.²⁸³

CLINICAL MANIFESTATIONS

Clinical manifestations of hypercalcemia depend on the rate of increase and absolute level of plasma calcium. The most serious manifestations are *neurologic* and *cardiovascular*. Patients may experience muscle weakness, fatigue, depression, and altered mental status. At extremely high levels, stupor and coma may ensue.^{225,230} Prolonged hypercalcemia lasting longer than 36 hours has been associated with the development of critical illness polyneuropathy and myopathy.²⁶⁸ Hypercalcemia causes an increased rate of cardiac repolarization and results in shortened QT interval. Conduction disturbances and malignant arrhythmias have been reported with hypercalcemia.^{284,285}

Hypercalcemia may lead to acute renal failure from volume depletion and renal vasoconstriction and polyuria and polydipsia due to NDI.^{225,230} GI symptoms include anorexia, nausea, vomiting, and constipation. Peptic ulcer disease and acute pancreatitis are exceedingly rare, especially in the acute setting.²²⁵

DIAGNOSIS

The diagnosis of hypercalcemia often is apparent from the history, with an understanding of the differential diagnosis (see [Box 57.11](#)). In cases of sustained or unexplained hypercalcemia, assays for intact PTH and vitamin D metabolites are of great value. An assay for PTHrP rarely is necessary in the evaluation of hypercalcemia in a critically ill patient, because in most patients with hypercalcemia of malignancy, the cancer is advanced and the diagnosis will be obvious when the PTH and vitamin D levels are shown to be suppressed.

TREATMENT

The treatment strategy for hypercalcemia depends on the severity of the disturbance and on its underlying cause. Identification of the probable cause of the hypercalcemia

is important both for the immediate and long-term management.

Mild hypercalcemia (total Ca \leq 12 mg/dL or 3 mmol/L) is usually caused by primary hyperparathyroidism, thiazide diuretics, calcium and vitamin D supplements, lithium, and immobilization. Treatment should begin with withdrawal of the offending agent (if possible). Volume deficits should be replaced orally if possible. Early mobilization should be encouraged. Loop diuretics should be avoided in patients with mild asymptomatic hypercalcemia as they may exacerbate the volume depletion, leading to increased renal calcium reabsorption.

The immediate treatment of moderate hypercalcemia (total Ca $>$ 12 mg/dL or 3 mmol/L, and \leq 14 mg/dL or 3.5 mmol/L) includes the measures discussed earlier, as well as intravenous volume expansion with isotonic saline. A loop diuretic will enhance renal excretion of calcium, but care must be taken to avoid volume depletion.

Severe hypercalcemia (total Ca $>$ 14 mg/dL or 3.5 mmol/L), even in the absence of signs and symptoms, should be treated as an emergency. Strategies for treatment include (1) enhanced calcium elimination; (2) reduced bone resorption; (3) decreased gut absorption of Ca; and (4) identification and treatment of the underlying cause.

Enhanced Calcium Elimination

Forced diuresis is the mainstay of treatment. *Volume expansion* with normal saline should be instituted immediately at a rate of 200 to 300 mL/hour. The net fluid balance in adults should be positive approximately 2 L in 24 hours. Caution must be taken to avoid symptomatic volume overload in patients with impaired myocardial performance and/or renal insufficiency.

Once the volume deficit is adequately replaced, *loop diuretics* should be added to enhance renal calcium excretion. A dose of loop diuretic that at least doubles the rate of urine output can be given as often as every 8 hours.

For patients with congestive heart failure unresponsive to diuretics, or with advanced kidney failure, *dialysis* should be considered. Hemodialysis against a solution containing 2.0 mEq/L calcium is very effective in decreasing plasma calcium levels. Lower calcium baths are likely to cause hypotension²⁸⁶ and precipitate tetany.

Reduced Bone Resorption

Several agents are available for the management of hypercalcemia. *Bisphosphonates* inhibit the osteoclast functions and number and inhibit bone turnover. They are well tolerated, although nephrotoxicity may develop if administered too quickly.²³⁰ Pamidronate (60-90 mg intravenously) reduces the plasma calcium in 48 to 72 hours and the effect may last for a month.²³⁰ Zoledronic acid may be even more efficacious.²⁸⁷ With the advent of bisphosphonates, two older agents have fallen into disfavor: *Calcitonin* has rapid onset of action but tachyphylaxis occurs within 48 to 72 hours. *Plicamycin* (formerly mithramycin) has unacceptable liver, renal, and bone marrow toxicity.

Decreased Gut Calcium Absorption

If endogenous vitamin D overproduction is implicated in the hypercalcemia (e.g., lymphoma, sarcoidosis),

corticosteroids will lower the plasma calcium, at least partly by decreasing gut calcium absorption.

MAGNESIUM HOMEOSTASIS

Disorders of magnesium balance may be the most commonly seen electrolyte abnormalities in the ICU. Hypomagnesemia, the more common disorder, is seen in 12% of hospitalized patients and up to 65% of critically ill patients.²⁸⁸⁻²⁹⁰ Because of magnesium's involvement in a host of critical physiologic functions,²⁹¹ its derangement can be expected to result in a variety of manifestations.

NORMAL MAGNESIUM PHYSIOLOGY

The normal adult total body magnesium content is approximately 24 g or 2000 mEq, 50% to 60% of which is found in bones and 40% to 50% in the intracellular compartment, mainly in the muscles and soft tissues. Only about 1% of total body magnesium is in the extracellular space, the normal concentration range being 1.8 to 2.3 mg/dL (1.5-1.9 mEq/L or about 0.7-1.0 mmol/L).²²⁸ In plasma, 20% to 30% of magnesium is bound to protein, mainly albumin, with the rest (70-80%) in a form that is filterable across the glomerulus.²²⁸ Magnesium is taken up slowly into cells, under no known hormonal control.

Magnesium is a major constituent of chlorophyll, and therefore green vegetables are a good dietary source. Also, magnesium is found in grains, cereals, meat, and seafood.^{228,292} The normal adult diet contains about 300 mg of magnesium.²⁹³ Under normal circumstances, about one third of that is absorbed in the small bowel; there is some obligatory secretion in that segment as well, along with some minor reabsorption downstream in the colon.²⁸⁸ This results in net absorption of about 100 mg/day. (Magnesium absorption is highly dependent on dietary magnesium content, however, and can increase to up to 70-80% of dietary intake under conditions of magnesium deprivation.²²⁸) Unlike calcium absorption, magnesium absorption from the intestine does not seem to depend significantly on vitamin D.^{228,294} The small intestinal secretion of magnesium normally amounts to a loss of only about 20 mg a day. With acute or chronic diarrhea, however, GI losses can be substantial.²²⁸

The filtered load of magnesium (the product of the glomerular filtration rate and the plasma concentration of ultrafilterable magnesium) is about 2500 mg/day. In order to maintain external magnesium balance, the renal excretion of magnesium must equal the intestinal absorption, or about 100 mg/day. Thus, the fractional excretion of magnesium ($Mg_{\text{excreted}} \div Mg_{\text{filtered}}$) is about 4% under normal conditions.²²⁸ With magnesium depletion, the fractional excretion of magnesium can fall to less than 1%, and with magnesium loading, it can rise to match the excess in the filtered load.²²⁸ This modulation in magnesium excretion is largely due to changes in plasma magnesium concentration.

The major site of renal magnesium reabsorption (60-70% of the filtered load) is the TAL. This tubular segment is responsible for most of the modulation in magnesium

excretion. Magnesium reabsorption here is largely passive and depends on a lumen-positive voltage generated by the (diuretic-inhibitable) NKCC2 channel and potassium recycling via the ROMK channels.²²⁸ This explains why loop diuretics increase urinary magnesium excretion and tend to cause hypomagnesemia. Other factors that inhibit magnesium reabsorption in the TAL include volume expansion, hypercalcemia, hypophosphatemia, and to a lesser extent metabolic acidosis. Conversely, volume depletion, hypocalcemia, and metabolic alkalosis increase magnesium reabsorption. About 10% of filtered magnesium is reabsorbed in the distal convoluted tubule. Reabsorption at this site is stimulated by potassium-sparing diuretics like amiloride.²⁸⁸

Magnesium plays a vital role in cellular physiology. It catalyzes over 300 enzymatic reactions and is an integral part of all ATP-dependent reactions.²⁹¹ It is involved in synthesis of proteins, energy-rich compounds, and electron and proton transporters; DNA and RNA transcription; translation of mRNA; and regulation of mitochondrial function.^{291,295} There is evidence that magnesium helps regulate intracellular calcium concentration, especially in vascular smooth muscle, and thereby affects vascular tone.²⁹⁵ In vitro studies suggest a role for magnesium in inflammation and immunity, though clinical confirmation is lacking.²⁹⁵

ASSESSMENT OF BODY MAGNESIUM STATUS

Because extracellular magnesium accounts for only about 1% of total body magnesium, plasma magnesium is a poor reflection of body magnesium status. Nonetheless, magnesium status is most commonly assessed by measuring plasma magnesium levels. Like calcium, magnesium circulates in the plasma in bound and free (ionized) forms, the latter being the metabolically active form. Determination of Mg^{2+} is clinically impractical, and there is no reliable correlation with serum albumin concentration. Moreover, the relationship between low Mg^{2+} concentration and increased morbidity and mortality rate in critically ill patients has yet to be clearly established.²⁹⁶⁻²⁹⁸ Thus, the available literature does not support the superiority of the measurement of Mg^{2+} over the cheaper and widely available total serum magnesium levels.

The magnesium loading test has been proposed as a more sensitive measure of total body magnesium stores than the plasma magnesium concentration. In theory, magnesium-depleted individuals will translocate more of the administered magnesium load into cells and excrete a lower proportion in the urine over 24 hours.^{266,288,295} Because the test requires a 24-hour urine collection, and must be limited to patients who have normal renal function and who are not on medications that affect magnesium excretion (see later), the test is impractical.

HYPOMAGNESEMIA

EPIDEMIOLOGY

Patients with malnutrition, chronic alcoholism, or congestive heart failure on loop diuretics; patients in the postoperative period (especially after open heart surgery); and patients with cancer are at higher risk than general ICU population.^{288-290,299}

CAUSES

The causes of hypomagnesemia can be divided into four main categories: (1) insufficient intake, (2) renal loss, (3) extrarenal loss, and (4) redistribution (Box 57.12).

The renal causes can be distinguished from the others by measuring 24-hour urinary magnesium excretion or, more practically, the fractional excretion of magnesium (FE_{Mg}), calculated as follows:²⁸⁸

$$FE_{Mg} = \frac{U_{Mg} \times P_{Cr}}{(0.7 \times P_{Mg}) \times U_{Cr}} \times 100$$

where U_{Mg} and P_{Mg} are the urine and plasma concentrations of Mg, respectively, and U_{Cr} and P_{Cr} are the urine and plasma concentrations of creatinine, respectively. (P_{Mg} is multiplied by 0.7, which represents the ultrafilterable fraction of magnesium.) A 24-hour urinary magnesium excretion of more than about 25 mg, or FE_{Mg} greater than 2%, is consistent with renal hypomagnesemia.^{225,288} Most hypomagnesemia in critically ill patients is multifactorial.

Redistribution

Acute pancreatitis
“Hungry bone” syndrome

Deficient Intake

The prevalence of hypomagnesemia in chronic alcoholics is approximately 20% to 30%. Hypomagnesemia in alcoholics is multifactorial and results from decreased dietary intake, increased renal loss, and acute pancreatitis.²⁸⁸ Parenteral nutrition is an important cause of hypomagnesemia in the ICU. Patients receiving parenteral nutrition have a higher daily magnesium requirement for unknown reasons.²²⁵

Gastrointestinal Losses

Diarrheal fluid contains high concentration of magnesium, up to 16 mg/dL,^{225,295} and hypomagnesemia is a common finding in patients suffering from acute or chronic diarrhea from any cause. Because intestinal absorption of magnesium occurs primarily in jejunum and ileum, conditions such as celiac disease, inflammatory bowel disease, extensive small bowel resection, and jejunioileal bypass surgery for obesity are frequently associated with intestinal magnesium wasting.²⁸⁸

Renal Losses

Medications are perhaps the most important cause of renal magnesium wasting in critically ill patients. Loop diuretics are commonly used at high doses. Aminoglycosides may cause asymptomatic hypomagnesemia 3 to 4 days after initiation of therapy; typically it resolves after cessation of therapy.^{225,300} Almost all patients who receive cisplatin develop renal magnesium wasting and hypomagnesemia, which may persist for months after discontinuation of therapy.³⁰¹ Most of the patients who receive intravenous pentamidine therapy develop renal magnesium wasting and hypomagnesemia that may last for 1 to 2 months after cessation of the therapy.²²⁵ The renal magnesium wasting associated with chronic alcohol use may take up to a month to resolve with abstinence.²⁸⁸

Redistribution

Hypomagnesemia is reported in up to 20% of patients with acute pancreatitis.^{290,295} The proposed mechanism is saponification of necrotic fat with magnesium and calcium. The mechanism of hypomagnesemia with the “hungry bone” syndrome (following parathyroidectomy for hyperparathyroidism) is rapid bone uptake of magnesium during remineralization.

CLINICAL MANIFESTATIONS

Hypomagnesemia in critically ill patients has been associated with a twofold increase in mortality rate, even after adjustment for severity of illness.³⁰² (The observation that magnesium supplementation has not been shown to improve outcome²⁸⁸ suggests that hypomagnesemia may be a marker for pejorative conditions not captured by severity of illness scores.)

The signs and symptoms of hypomagnesemia are cardiovascular, neuromuscular, and metabolic, and are shown in Box 57.13.^{225,288,291,295} There is little evidence that hypomagnesemia is associated with arrhythmias in otherwise healthy individuals. In the setting of acute myocardial ischemia, however, even mild hypomagnesemia has been associated with increased frequency of ventricular arrhythmias.²⁸⁸ Results of recent large clinical trials, however, have shown no benefit to magnesium supplementation in this setting in the absence

Box 57.13 Clinical Manifestations of Hypomagnesemia**Cardiovascular**

 Hypocalcemia, refractory

of overt hypomagnesemia.²⁹⁵ Torsades de pointes is a malignant ventricular arrhythmia associated with magnesium deficiency or drugs that prolong the QT interval. Magnesium is the treatment of choice. Magnesium supplementation after cardiopulmonary bypass may reduce the frequency of ventricular ectopy.

The hypocalcemia associated with hypomagnesemia is caused by both hypoparathyroidism and bone resistance to PTH. The hypokalemia is caused by renal potassium wasting and will not resolve until the hypomagnesemia is corrected.^{303,304}

TREATMENT

In patients who have malignant cardiac arrhythmias (ventricular fibrillation or torsades de pointes) or seizure attributed to hypomagnesemia, intravenous magnesium (2 g of magnesium sulfate over minutes) must be given immediately (see Chapter 31 for details).

Less urgent cases, but those in which signs and symptoms are present, may be treated with magnesium sulfate 6 g intravenously in the first 24 hours followed by 3 to 4 g daily for the next 2 to 6 days.^{225,288,295} Because translocation of magnesium into cells is a slow process, and because urinary excretion is proportional to the plasma magnesium level, more rapid infusion rates are associated with urinary magnesium wasting that defeats the purpose of the therapy. Effective intravenous infusions should be given over 8 to 12 hours.²⁸⁸ For patients with impaired renal function, the dose should be reduced by 50% to 75% and serum magnesium levels should be monitored frequently. Patients should be monitored closely for symptoms and signs of hypermagnesemia (see later).

Patients with refractory hypokalemia in the setting of hypomagnesemia, who are receiving high doses of potassium, must be monitored closely for the development of hyperkalemia once the magnesium is being replenished.

Box 57.14 Causes of Hypermagnesemia**Patients with Renal Insufficiency**

Magnesium-containing antacids (e.g., magnesium aluminum hydroxide)
 Magnesium-containing laxatives or enemas (e.g., magnesium citrate)

Patients with Normal Renal Function

Treatment of preeclampsia or eclampsia
 Treatment of hypomagnesemia

Miscellaneous

Hypothyroidism
 Hyperparathyroidism
 Addison's disease
 Lithium treatment

For mild asymptomatic hypomagnesemia, patients who can tolerate oral medication should receive oral magnesium salts (e.g., magnesium chloride, 500 mg slow release tablets, 10-12 per day in divided doses). High doses of oral magnesium salts may cause diarrhea.

HYPERMAGNESEMIC**CAUSES**

Hypermagnesemia is much less common than hypomagnesemia. Patients with normal renal function have prodigious capacity to excrete excess magnesium through the kidneys.²²⁵ Thus, hypermagnesemia is seen only in patients with compromised renal function receiving enteral or parenteral Mg or in patients with normal renal function receiving massive exogenous magnesium (e.g., treatment for preeclampsia and eclampsia).²²⁵ The causes of hypermagnesemia are shown in Box 57.14.

CLINICAL MANIFESTATIONS

The clinical manifestations of hypermagnesemia (Box 57.15) are largely due to the effects on the heart, nerve, and smooth muscle. Initial manifestations, with plasma concentrations of 4 to 6 mg/dL, include nausea and vomiting, hypotension, and flushing. More severe effects, including death,³⁰⁵ are seen with levels exceeding 6 mg/dL.

TREATMENT

Treatment of hypermagnesemia depends on severity of symptoms and the patient's renal function. Patients with adequate renal function and mild asymptomatic hypermagnesemia require no treatment except to remove all sources of exogenous magnesium. The half-time of elimination of magnesium is about 28 hours.²²⁵ Magnesium excretion may be enhanced by saline infusion and the use of loop diuretics.²²⁵ (Care must be taken to prevent hypokalemia and metabolic alkalosis.) Patients with symptomatic hypermagnesemia, especially with cardiovascular manifestations, require urgent treatment. The recommended therapy is calcium gluconate 1 g intravenously over 5 minutes.

Patients with acute or chronic renal failure and symptomatic hypermagnesemia will require dialysis to remove excess

magnesium. Hemodialysis removes magnesium efficiently, yielding a 30% to 50% reduction in predialysis serum magnesium levels after a 3- to 4-hour treatment.²²⁵

PHOSPHORUS HOMEOSTASIS

Phosphorus has an essential role in normal physiology. It is necessary for skeletal integrity; energy economy (formation of high-energy phosphate bonds); nucleic acid, lipid, and protein structure; cell signaling; and buffering.²²⁸ It is not surprising, therefore, that disorders of phosphorus homeostasis have diverse manifestations.³⁰⁶⁻³⁰⁸ Hypophosphatemia is considerably more common in hospitalized and critically ill patients than hyperphosphatemia.

NORMAL PHOSPHORUS HOMEOSTASIS

Total body phosphorus amounts to about 700 g in an adult. About 85% resides in the skeleton, about 15% in soft tissues, and only about 1% in blood.²²⁷ Circulating phosphorus is mostly in the form of inorganic phosphates. The normal plasma concentration of phosphorus is 2.5 to 4.5 mg/dL, also expressed as a phosphate concentration of 0.9 to 1.45 mmol/L. (Phosphate concentration should not be expressed in mEq/L because the average valence of plasma phosphates—a mixture of HPO_4^{2-} and H_2PO_4^- —changes with pH.³⁰⁹) Of that circulating phosphorus, about 75% is free and ultrafilterable; 25% being protein bound.²²⁸

A normal adult diet includes about 1000 mg of phosphorus per day. Stool contains about 300 mg, so the net absorption (mostly in the small intestine under the influence of vitamin D) is about 70%. The dietary and secreted phosphorus may be bound into insoluble, nonabsorbable salts by cations such as Al^{3+} , Ca^{2+} , and Mg^{2+} . Thus, the kidney is responsible for excreting about 700 mg phosphorus per day. Almost all phosphorus reabsorption takes place in the proximal tubule. The most important regulators of renal phosphorus excretion are PTH, fibroblast growth factor (FGF)-23, and dietary phosphorus content. PTH increases phosphorus excretion.²²⁷ FGF-23, a phosphatonin released

by osteocytes and osteoblasts in bone, increases urinary phosphorus excretion.³¹⁰ Renal excretion of phosphorus is proportional to the dietary intake. Other factors that increase renal phosphorus excretion include extracellular volume expansion, acute hypercalcemia, diuretics, and glucocorticoids.^{227,228} Acid-base disorders have a variable effect on phosphorus reabsorption depending on their direction and duration,^{227,228} with one exception: Respiratory alkalosis causes a marked decrease in renal phosphorus excretion by causing redistributive hypophosphatemia³⁰⁷ (see later).

Phosphorus homeostasis depends on PTH, FGF-23, and vitamin D. PTH and FGF-23 cause phosphaturia by decreasing renal proximal tubule reabsorption. Active vitamin D inhibits PTH release. Vitamin D activation (1- α -hydroxylation) in the kidney is inhibited by FGF-23 and hyperphosphatemia. This, in turn, reduces intestinal phosphorus absorption and allows increased PTH secretion, causing phosphaturia and returning plasma phosphorus toward normal. Hypophosphatemia reverses this physiology, allowing increased gut absorption and reduced renal excretion of phosphorus.

HYPOPHOSPHATEMIA

Hypophosphatemia is common in critically ill patients. It has been reported in 29% of adult surgical patients (and 45% of patients with one or more risk factors for hypophosphatemia) and—liberally defined—in 76% of pediatric ICU patients.³¹¹ Patients with malnutrition, uncontrolled diabetes mellitus, sepsis, and chronic alcoholism are at high risk for hypophosphatemia.³¹² It is associated with a marked increase in mortality rate in patients with sepsis,³¹³ and serum phosphorus concentration is inversely correlated with APACHE II after liver resection.³¹⁴ In these situations, the serum phosphorus concentration probably is a marker of severity of illness. If severe, however, hypophosphatemia itself may cause serious complications.

CAUSES OF HYPOPHOSPHATEMIA

The causes of hypophosphatemia classically are divided into three general categories: (1) redistribution from the extracellular to the intracellular space, (2) increased renal excretion, and (3) decreased intestinal absorption (Box 57.16). It is important to recognize that many factors have several different effects on phosphorus homeostasis.

Redistribution

Respiratory alkalosis causes intracellular phosphate shift (by stimulating glycolysis) and can cause severe symptomatic hypophosphatemia. Respiratory alkalosis is commonly encountered in ICU patients because of sepsis or liver failure and is seen in patients requiring mechanical ventilation; in the latter case, the degree of hypophosphatemia is proportional to the pH.^{225,315} *Sepsis* is commonly associated with hypophosphatemia, probably due to hyperventilation and respiratory alkalosis. Rapid *refeeding* of patients with malnutrition may result in significant hypophosphatemia due to insulin-mediated intracellular phosphate shift. In one study of ICU patients, refeeding hypophosphatemia developed in 34% of patients after 48 hours of starvation and was predicted by the prealbumin concentration. Profound hypophosphatemia (<1 mmol/dL) occurred in 10%

of patients.³¹⁶ Patients with anorexia nervosa, uncontrolled diabetes mellitus, chronic malnutrition, and chronic alcoholism are at a particularly high risk of developing refeeding syndrome. *Leukemia* in the leukemic phase³¹⁷ and with rapid leukocyte reconstitution after bone marrow transplant³¹⁸ has been reported to cause severe redistributive hypophosphatemia.

DKA is associated with phosphorus efflux from cells and increased urinary phosphate excretion, resulting in severe total body phosphorus depletion (often with a deceptively normal presenting serum phosphorus concentration).³⁰⁷ Initiation of insulin therapy in such patients results in intracellular phosphate shift and can result in profound, symptomatic hypophosphatemia.³⁰⁷

Increased Renal Excretion

Any cause of *primary hyperparathyroidism* will cause phosphaturia and tend to cause hypophosphatemia. Hyperparathyroidism due to hypocalcemia or *vitamin D deficiency* or *resistance* is similarly associated with hypophosphatemia. The exception is the secondary hyperparathyroidism of chronic kidney disease, in which hyperphosphatemia due to decreased renal phosphorus elimination is characteristic. Vitamin D deficiency or resistance also causes hypophosphatemia from decreased intestinal phosphate absorption. Extracellular volume expansion increases the filtered phosphorus load and dilutes the luminal concentration of phosphorus, resulting in phosphaturia. *Ethanol* and *glycosuria* both decrease proximal tubule phosphate reabsorption.^{225,307} All *diuretic drugs*, but particularly those with proximal tubular effects such as acetazolamide and, to a lesser degree, thiazides, cause phosphaturia.

Decreased Intestinal Absorption

Salts of Al^{3+} and Ca^{2+} , formulated for oral administration as antacids or as phosphate-binding medications, can cause malabsorptive hypophosphatemia. Chronic diarrhea and steatorrhea may cause reduced intestinal phosphate absorption directly and by way of vitamin D deficiency and cause hypophosphatemia.

The hypophosphatemia commonly associated with *chronic alcohol ingestion* is multifactorial. Dietary phosphorus deficiency, malabsorption, antacid ingestion, hypocalcemia, secondary hyperparathyroidism, hypomagnesemia, and an ethanol-induced renal tubular defect all have been implicated.³⁰⁷

CLINICAL MANIFESTATIONS

Important clinical manifestations of hypophosphatemia are shown in [Box 57.17](#). Most patients are asymptomatic until plasma phosphorus falls below 1.5 mg/dL or about 0.5 mmol/L. The most severe manifestations, such as hemolysis, spontaneous rhabdomyolysis, seizure, or coma, are not commonly seen with phosphorus above 1 mg/dL (0.3 mmol/L). Acute clinical manifestations are thought to be largely due to altered cellular energy economy.^{225,227,306,307}

TREATMENT

The therapy of hypophosphatemia starts with its prevention. In critically ill patients, this depends on recognition and correction of the factors that lead to hypophosphatemia. The astute clinician will be able to anticipate the development of hypophosphatemia (in refeeding, for example), monitor the patient appropriately, and supplement phosphorus accordingly. Patients on total parenteral nutrition

should receive adequate phosphorus for their level of renal function (see Chapter 82).³⁰⁹

The exact method of phosphorus supplementation in hypophosphatemia depends on the severity of the disturbance and the patient's underlying condition. In mild to moderate hypophosphatemia (>1.5 mg/dL or about 0.5 mmol/L) oral replacement is usually sufficient. Skim milk is an excellent source of phosphorus and provides 900 mg/L of inorganic phosphate. In patients who cannot tolerate milk, oral sodium phosphate, formulated to provide 250 mg of phosphate in each tablet, can be used. Alternatively, Fleet Phospho-soda can be given to provide 60 mmol of phosphorus per day, divided into three doses of 5 mL each.²²⁷ Supplementation should continue for several days in order to replenish phosphorus deficits adequately. Administration of sufficient doses of oral phosphorus preparations very commonly causes diarrhea, limiting its usefulness.

Patients with severe hyperphosphatemia (<1.5 mg/dL), or those for whom the enteral route is not an option, require intravenous phosphorus repletion. In such patients, the recommended dose is 2.5 to 5.0 mg (0.08–0.16 mmol) per kg body weight over 6 hours, doses at the higher end of the range being reserved for profound, symptomatic hypophosphatemia.^{227,309} A recent study used a more aggressive, weight-based protocol in critically ill patients and found it to be safe and effective.³¹⁹ Clinicians should recognize that the administered intravenous phosphorus can complex with circulating calcium, leading to a decrease in Ca^{2+} (with attendant hypotension and tetany) and metastatic calcification. The use of potassium salts of phosphate for repletion of phosphorus deficits has been associated with dangerous hyperkalemia. For that reason, potassium deficits and phosphorus deficits should be treated separately.³⁰⁹

HYPERPHOSPHATEMIA

Hyperphosphatemia (plasma phosphorus >5.0 mg/dL or a phosphate concentration >1.6 mmol/L) most often is associated with renal dysfunction. Massive influx of phosphorus into the extracellular space, however, either from endogenous sources or exogenous, can overwhelm normal renal excretory mechanisms and lead to severe hyperphosphatemia.

CAUSES OF HYPERPHOSPHATEMIA

Hyperphosphatemia may be caused by (1) redistribution of phosphorus from the intracellular to the extracellular space, (2) increased phosphorus intake, and (3) decreased renal excretion of phosphorus (Box 57.18). It is important to recognize that most hyperphosphatemia is multifactorial.

Redistribution

Hyperphosphatemia is a common complication of the *tumor lysis syndrome*.⁷² Similarly, rhabdomyolysis often is associated with hyperphosphatemia, especially when it is complicated by acute renal failure.^{74,320} Less commonly recognized causes of redistributive hyperphosphatemia include acute and chronic respiratory acidosis, acute pancreatitis,³²¹ DKA,³²² and lactic acidosis.³²³

Box 57.18 Causes of Hyperphosphatemia

Redistribution
 Tumor lysis syndrome
 Rhabdomyolysis
 Pancreatitis
 Respiratory acidosis
 Lactic acidosis
 Diabetic ketoacidosis
 Increased intake
 Phosphate-containing enemas and laxatives
 Intravenous phosphate
 Hypervitaminosis D
 Decreased renal excretion
 Acute renal failure
 Chronic kidney disease
 Hypoparathyroidism
 Pseudohyperphosphatemia

Increased Intake

Exogenous administration of phosphorus is unlikely to cause hyperphosphatemia unless renal function is compromised. Several cases have been reported of potentially life-threatening hyperphosphatemia and hypocalcemia after the use of phosphate-containing laxatives and enemas, especially in children and elderly.* Overly aggressive parenteral phosphorus supplementation can cause hyperphosphatemia. Hypervitaminosis D causes increased intestinal uptake of phosphorus and a decrease in PTH, both of which predispose to hyperphosphatemia.

Decreased Renal Excretion

Acute renal failure is associated with elevated phosphate levels due to inability of kidneys to excrete phosphate load. This is particularly pronounced in patients in whom acute renal failure is caused by the tumor lysis syndrome or rhabdomyolysis. Advanced chronic kidney disease (GFR <25 mL/minute) commonly is associated with hyperphosphatemia. Such patients are particularly susceptible to developing severe and life-threatening hyperphosphatemia if they are exposed to acute increase in serum phosphate levels. Hypoparathyroidism of any cause is associated with impaired renal phosphorus excretion.

Pseudohyperphosphatemia

Spurious increases in the measured plasma phosphorus concentration are reported to be caused by contamination of the blood sample with phosphate-buffered saline as a diluent for heparin³²⁶ or during sample processing by the laboratory.³²⁷ Even microliter volumes of the contaminant can cause significant elevations in the measured phosphorus.³²⁶ Paraproteinemia can also cause pseudohyperphosphatemia.

CLINICAL MANIFESTATIONS OF HYPERPHOSPHATEMIA

Phosphate complexes with circulating calcium, reducing the concentration of Ca^{2+} . Thus, most of the clinical

*248, 250, 251, 324, 325.

consequences of hyperphosphatemia are the same as those of hypocalcemia (see earlier). In addition, ectopic deposition of calcium phosphate salts can occur, especially when the calcium-phosphorus product exceeds 70 mg/dL.²²⁷ Such ectopic calcification in the heart can cause conduction and rhythm disturbances.³²⁸

Because phosphate is an “unmeasured ion,” hyperphosphatemia causes increases in the anion gap. Extreme hyperphosphatemia can cause shocking elevations in the anion gap. One case of hyperphosphatemia from Phospho-soda intoxication (serum phosphorus 62.5 mg/dL) was associated with an anion gap of 51 mmol/L.³²⁹ In order to estimate the contribution of phosphorus to the anion gap, one must know not only the plasma concentration of phosphorus but the pH, because the valence of phosphate varies with pH, from 1.8 mEq/mmol at pH 7.4 to 1.6 mEq/L at pH 7.0.³⁰⁹ Because extreme hyperphosphatemia can be caused by lactic or ketoacidosis (see earlier), an elevated anion gap in the setting of hyperphosphatemia should never be attributed to the hyperphosphatemia itself without further investigation.

TREATMENT OF HYPERPHOSPHATEMIA

Treatment of hyperphosphatemia consists of reducing the phosphate intake and enhancing the removal of excess phosphate. If the patient is taking oral diet, dietary phosphate should be restricted to less than 800 mg/day. Oral phosphate binders can be added with meals to decrease intestinal phosphate absorption.

Patients with normal renal function can be treated with saline diuresis to increase renal phosphate excretion. Acetazolamide can be added to enhance phosphaturia, taking care to avoid a metabolic acidosis. Patients with severe hyperphosphatemia with coexisting renal failure may require renal replacement therapy in the form of intermittent or continuous hemodialysis.

KEY POINTS

- Acid-base disorders often provide a window into underlying pathology. Optimal diagnosis of acid-base disorders requires familiarity with the rules of normal compensation and the pitfalls characteristic of critical illness.
- Acute hyperkalemia may result from exogenous potassium administration or redistribution from cells. Acute hypokalemia always is caused by redistribution.
- Patients, particularly women, are predisposed to catastrophic hyponatremia if hypotonic fluids are administered in the postoperative period.
- The treatment of acute symptomatic hyponatremia is largely independent of its cause, whereas the treatment of chronic hyponatremia depends critically on the underlying pathophysiology.

KEY POINTS (Continued)

- Hyponatremia in hospitalized patients should be considered iatrogenic, reflecting insufficient recognition of the causes of water loss and inadequate water replacement in vulnerable patients.
- Plasma calcium concentration, corrected for the plasma albumin concentration, correlates poorly with Ca^{2+} in critically ill patients. If possible, Ca^{2+} should be directly measured when considering disorders of calcium homeostasis.
- The clinical manifestations of many metabolic disorders have common features (e.g., hypocalcemia, hypomagnesemia, hyperphosphatemia, metabolic alkalosis) relating to their overlapping pathophysiology.

DIABETES MELLITUS: EPIDEMIOLOGY AND CLASSIFICATION

Diabetes mellitus (DM) is the fourth to fifth most common cause of death in developed countries and is one of the most common noncommunicable diseases globally.¹ DM affects nearly 27 million individuals in the United States and 366 million adults aged 20 to 79 years worldwide.² Nearly half of those with diabetes are undiagnosed.² The worldwide incidence of DM is expected to reach 552 million by 2030 with the prevalence of diabetes increasing in every country.² Diabetes is the leading cause of kidney failure, nontraumatic lower limb amputations, and new cases of blindness among adults in the United States, and is a major cause of heart disease and stroke.³

Diabetes is generally classified as follows:

1. *Type 1 diabetes*—autoimmune β -cell destruction resulting in an absolute insulin deficiency
2. *Type 2 diabetes*—progressive defects resulting in increased insulin resistance and a relative insulin deficiency
3. *Gestational diabetes*—diabetes appearing during pregnancy
4. *Diabetes due to other causes*—such as genetic defects in β -cell function, genetic defects in insulin action, diseases

of the exocrine pancreas (such as cystic fibrosis, pancreatitis, or pancreatectomy), and drug- or chemical-induced diabetes⁴

Type 2 diabetes accounts for 90% to 95% of DM in the United States.³ The epidemic of type 2 DM has been attributed to the increasing rates of obesity.

In patients with diabetes, absolute or relative insulin deficiency leads to hyperglycemia from decreased glucose utilization in peripheral tissues (especially skeletal muscle) and increased hepatic glucose output from glycogenolysis and gluconeogenesis.⁵ Proteolysis and lipolysis are also increased, providing the amino acids and free fatty acids that are the substrate for gluconeogenesis and alternative fuel sources such as ketones. The various actions of insulin are shown in Box 58.1.⁶

DIABETIC KETOACIDOSIS AND THE HYPERGLYCEMIC HYPEROSMOLAR STATE

Diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar state (HHS) are both part of an overlapping process of decompensated hyperglycemia.⁷ A significant imbalance between insulin and its counterregulatory hormones

Table 58.1 Diagnostic Criteria for Diabetic Ketoacidosis (DKA) and Hyperglycemic Hyperosmolar Syndrome (HHS)

Criterion	DKA			HHS
	Mild	Moderate	Severe	
Plasma glucose (mg/dL)	>250	>250	>250	>600
Arterial pH	7.25-7.3	7-7.24	<7	>7.3
Serum bicarbonate (mEq/L)	15-18	10-<15	<10	>15
Urine ketones*	Positive	Positive	Positive	Small
Serum ketones*	Positive	Positive	Positive	Small
Effective serum osmolality (mOsm/kg) [†]	Variable	Variable	Variable	>300
Anion gap	>10	>12	>12	Variable
Alteration in sensorium or mental obtundation	Alert	Alert/drowsy	Stupor/coma	Stupor/coma

*Nitroprusside reaction method.

Box 58.1 Actions of Insulin on Target Organs

Adipose Tissue

Increased glucose entry
Increased fatty acid synthesis
Increased glycerol phosphate synthesis
Increased triglyceride deposition
Activation of lipoprotein lipase
Inhibition of hormone-sensitive lipase

Liver

Decreased ketogenesis
Increased protein synthesis
Increased lipid synthesis
Decreased glucose output via increased glycogen synthesis and decreased gluconeogenesis

Muscle

Increased glucose entry
Increased glycogen synthesis
Increased amino acid uptake
Increased protein synthesis in ribosomes
Decreased protein catabolism
Decreased release of gluconeogenic amino acids
Increased ketone uptake
Increased K⁺ uptake

General

Increased cell growth

From Barrett KE, Barman SM, Boitano S, Brooks H: Endocrine functions of the pancreas and regulation of carbohydrate metabolism. In Barrett KE, Barman SM, Boitano S, Brooks H (eds): *Ganong's Review of Medical Physiology*, 23rd ed. New York, McGraw-Hill, 2010, Chap. 21.

(especially glucagon) leads to DKA, a severe metabolic state of hyperglycemia and acidemia from abnormal metabolism of fats, lipids, and carbohydrates.⁸ DKA is common complication of type 1 DM and is also seen, albeit less frequently, in type 2 DM. The combined findings of serum glucose

greater than 250 mg/dL, a pH less than 7.30 with an elevated anion gap, and elevated serum ketones are consistent with DKA.

HHS is a state of hyperglycemia associated with osmotic diuresis and dehydration. HHS is defined by glucose levels greater than 600 mg/dL, an elevated serum osmolality, a lack of significant acidemia or ketosis, and typically a change in mental status. HHS has replaced the term “hyperglycemic, hyperosmolar nonketotic coma” because patients may present with a mild elevation in urine or serum ketones and may have a variety of mental status changes other than coma. A careful evaluation of history, physical examination, and laboratory values helps differentiate DKA from HHS (Table 58.1) and assists in distinguishing DKA and HHS from other conditions with overlapping clinical presentation.⁹

EPIDEMIOLOGY

DKA has high morbidity rates, mortality rates, and financial costs despite numerous advances in the treatment of DM. The incidence of DKA in the United States is estimated at 5.9 to 12.9 cases per 100,000 people.^{10,11} The 120,000 patients admitted to the hospital for DKA each year¹² account for approximately \$1.4 billion in hospital reimbursement.¹³ DKA carries a mortality rate of 1% to 5%.^{9,14} Though the highest mortality rate is in the elderly and in patients with comorbid conditions, DKA remains the leading cause of death in diabetic patients below the age of 24.¹⁵

Although most patients will have a history of diabetes, 27% to 37% of patients with DKA carry no prior diagnosis.^{16,17} This is especially true in young children.¹⁸ Although the development of DKA is classically associated with type 1 DM, some patients lack the classic clinical presentation, autoimmune markers, or diminished β -cell reserve of type 1 diabetes.¹⁹⁻²¹ This subgroup, known as “ketosis-prone type 2 diabetes,” represents patients with type 2 DM who present with DKA and often are African American or Latino, male, middle-aged, and overweight or obese; have a family history of diabetes; and have newly diagnosed diabetes.^{22,23} Patients with ketosis-prone type 2 DM account for 1 in 5 cases of

DKA.²² Patients with “classic” type 2 diabetes may also develop DKA in situations of extreme stress.

HHS occurs far less commonly than DKA, with an estimated prevalence of 1 in 1000,²⁴ though the increasing incidence of type 2 DM is expected to increase the prevalence of HHS. HHS typically occurs in patients with type 2 DM and 30% to 40% cases of HHS may be the initial finding leading to diagnosis of type 2 DM.^{25,26} The mortality rate in HHS tends to be higher than in DKA, with the patient’s comorbid conditions and severity of presentation significantly affecting risk of death.²⁷

PATHOPHYSIOLOGY

The pathophysiology of DKA is driven by insulin deficiency and a rise in the counterregulatory hormones, particularly glucagon, but also epinephrine, cortisol, and growth hormone (Fig. 58.1).^{28,29} Insulin deficiency results in decreased glucose uptake by peripheral tissues, resulting in elevated serum glucose levels, and hyperglycemia worsens when an increase in glucagon (and an imbalanced insulin/glucagon ratio) results in unrestrained hepatic

glycogenolysis and gluconeogenesis.^{9,24,28} Osmotic diuresis results in total body loss of water and electrolytes, causing intravascular volume depletion. Cellular dehydration occurs as water and electrolytes move from the intracellular to extracellular space. With volume depletion, impaired renal function limits the clearance of glucose and worsens the hyperglycemia.^{9,24} In an insulin-deficient state proteolysis and lipolysis drive accelerated gluconeogenesis as amino acids and free fatty acids are shunted to the liver.³⁰ At the same time, oxidation of free fatty acids results in the production of the keto acids acetoacetate and β -hydroxybutyrate.^{9,24} These weak acids react with bicarbonate and diminish the body’s bicarbonate stores. The development of metabolic acidosis in DKA results when the increase in acid production exceeds the body’s buffering capacity.³¹

HHS is also caused by a relative insulin deficiency and a rise in counterregulatory hormones. Decreased peripheral glucose uptake and increased glycogenolysis and gluconeogenesis result in hyperglycemia followed by osmotic diuresis with volume depletion and dehydration. However, the amount of insulin is sufficient to limit the oxidation of free fatty acids,⁹ and significant keto acid production does not

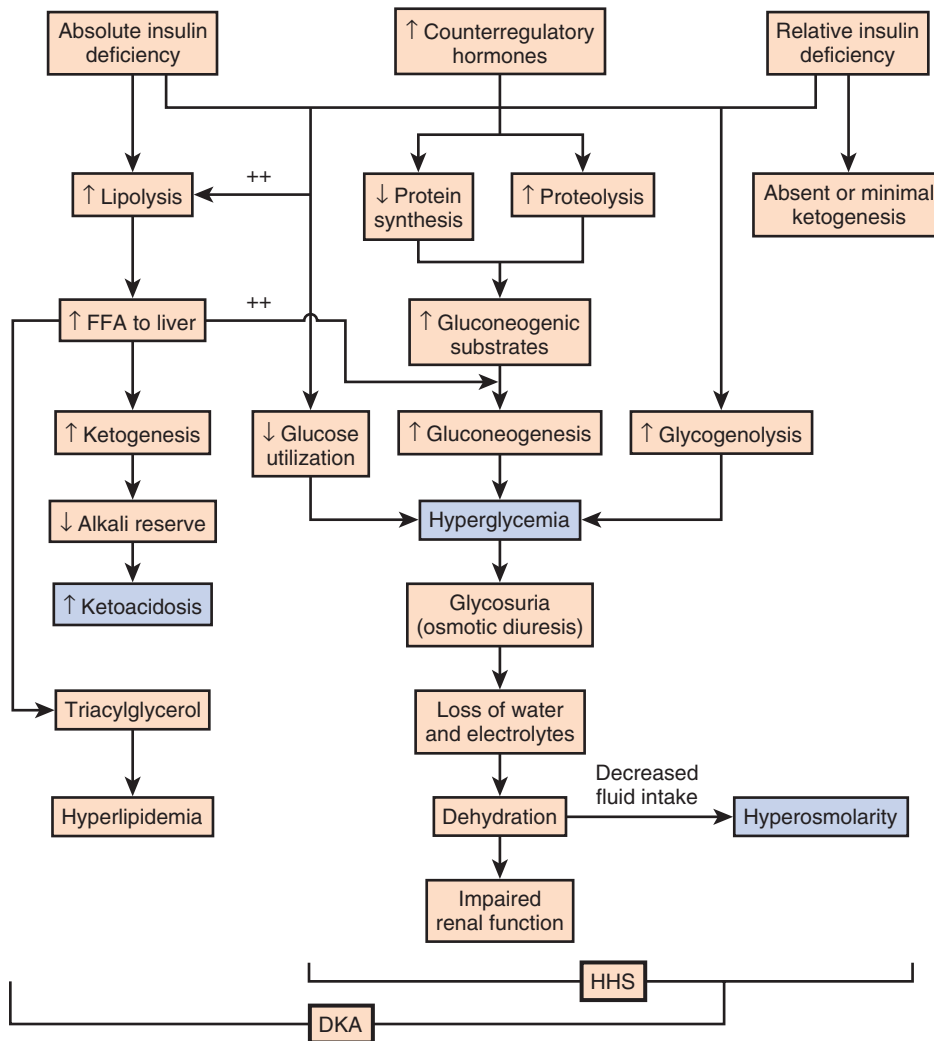

Figure 58.1 Pathogenesis of diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar state (HHS): stress, infection, or insufficient insulin. FFA, free fatty acid. (From Kitabchi AE, Umpierrez GE, Miles JM, Fisher JN: Hyperglycemic crises in adult patients with diabetes. *Diabetes Care* 2009;32(7):1335-1343.)

occur. In the absence of ketoacidosis, the process of dehydration is allowed to continue for longer than in DKA, and patients present with significant hyperosmolarity.

PRECIPITATING FACTORS

The precipitating factors for the development of DKA and HHS are listed in the [Table 58.2](#). Omission of antidiabetic medications is an important factor in the development of DKA and HHS. Omission of insulin may result in DKA in a patient with type 1 diabetes in a matter of hours. In contrast, the development of HHS (or DKA) in a patient with type 2 diabetes occurs over days to weeks in a patient omitting insulin or oral agents. In addition to the factors listed in the table, impaired thirst or lack of access to water, particularly in the elderly, will contribute to the development of HHS.³² Eating disorders may account for up to 20% of cases of recurrent DKA.⁹

PRESENTATION

The presentation of DKA and HHS varies with the severity of the metabolic derangement and any intercurrent illnesses or comorbid conditions. DKA can occur in a patient without a history of diabetes who presents with only mild symptoms; a high index of suspicion is needed to make the diagnosis in this setting, particularly in children under the age of 6. A detailed evaluation should reveal precipitating factors, especially infection and medication nonadherence, which are common triggers of DKA and HHS (see [Table 58.2](#)).²⁴ Patients may present with symptoms of hyperglycemia (polyuria, polyphagia, polydipsia, or blurred vision) or with nonspecific symptoms of fatigue, abdominal pain, nausea, vomiting, and headache. Mental status can vary from somnolence to lethargy and even coma as the acidosis or hyperosmolarity worsens. Volume depletion may be manifested by tachycardia, poor skin turgor, dry mucous membranes, and orthostatic hypotension. In patients with DKA, metabolic acidosis causes rapid deep breathing (known as Kussmaul respiration), and acetone (derived from acetoacetate) can be sensed as a fruity smell on the patient's breath.

DIAGNOSIS

The diagnosis of DKA is based on a serum glucose level greater than 250 mg/dL, presence of ketones, arterial pH less than 7.3, and a CO₂ concentration less than 18 mmol/L.^{5,9} The anion gap will be elevated, reflecting the presence of the unmeasured keto acids. The laboratory findings and changes in mental status help the clinician gauge the severity of DKA and distinguish DKA from HHS. Although arterial blood had previously been the standard for determining pH, current evidence supports the use of venous pH as a less expensive, more accessible alternative.^{33,34} Exceptions to the typical presentation include pregnant patients or those with poor oral intake who may have a serum glucose value below 250 mg/dL, or even in the normal range.^{35,36} In patients with severe vomiting, the bicarbonate value may be normal or elevated.

The serum sodium may be normal, low, or elevated depending on the degree of dehydration and hyperglycemia. Patients with hyperglycemia have dilutional hyponatremia from a shift in fluids from the intracellular to extracellular compartment. The serum sodium may be “corrected” for hyperglycemia (i.e., adjusted to estimate the serum sodium concentration once the hyperglycemia has resolved) by adding 1.6 mEq/L to the measured sodium for every 100 mg/dL of plasma glucose above 100 mg/dL. As the measured serum sodium will underestimate the “corrected” sodium level in patients, measured serum sodium in the “normal” range may represent significant dehydration and hyponatremia.

The serum potassium level may also be normal, low, or elevated depending on factors such as the degree of acidosis or osmotic diuresis and the duration of the process. Insulin deficiency and acidosis decrease cellular uptake of potassium, although hyperosmolality enhances cellular efflux of potassium.³⁷ Large amounts of potassium shift from the intracellular space to the extracellular space and are then lost in the urine. Regardless of the serum potassium level, all patients with DKA and HHS have substantial depletion of total body potassium.^{9,37,38}

The serum osmolality (in mOsm/kg) can be estimated by the following calculation:

Table 58.2 Causes of Diabetic Ketoacidosis and Hyperglycemic Hyperosmolar Syndrome

Etiologic Factor/Condition	Diagnoses with Comments
Inadequate insulin	Nonadherence, ^{25,193,194} inadequate insulin regimen, ³⁴ insulin pump failure or omission of insulin, ^{195,196} new-onset diabetes ¹⁹⁷
Infections	Any moderate to severe infectious process ^{29,198} Most commonly, pneumonia, urinary tract infection, sepsis ⁹
Acute medical conditions	Myocardial infarction, ⁹ pancreatitis, ⁴¹ cerebrovascular accident, ⁹ arterial thrombosis (mesenteric, iliac) ¹⁹⁹
Interference with glucose metabolism or insulin secretion ³²	Thiazide diuretics, corticosteroids, ²⁰⁰ second-generation (atypical) antipsychotics, ²⁰¹ FK506, ²⁰² glucagon, ²⁰³ sympathomimetic agents (albuterol, terbutaline, dobutamine) ²⁰⁴
Endocrine disturbance	Pheochromocytoma, ²⁰⁵ hyperthyroidism, ²⁰⁶ acromegaly, ²⁰⁷ hemochromatosis ²⁰⁸
Substance abuse	Cocaine ²⁰⁹
Nutritional factors	Parenteral nutrition ²¹⁰

$$2[\text{measured Na}^+] + [\text{glucose (mg/dL)}]/18] + [\text{BUN (mg/dL)}]/2.8]$$

Serum osmolality is generally normal or mildly elevated in DKA but is often profoundly elevated in patients with HHS.

Semiquantitative nitroprusside assays for urine and serum ketones are commonly employed but test only for acetone and acetoacetate, not β -hydroxybutyrate. This can be problematic, although β -hydroxybutyrate is the predominant keto acid, accounting for 75% of the keto acid load in DKA.³⁹ In addition, nitroprusside assays may remain positive long after resolution of the metabolic acidosis, so serial measurements may be misleading and are not recommended. Quantitative assays for β -hydroxybutyrate are available and may be useful for diagnosis, especially if the nitroprusside test is negative. A small pilot study found that a serum level above 3.5 mmol/L has 100% specificity for DKA.⁴⁰ Unlike the nitroprusside assay, the β -hydroxybutyrate test can also be used to monitor the management of DKA because appropriate treatment will be accompanied by a progressive fall in β -hydroxybutyrate levels.

The diagnostic criteria that distinguish HHS from DKA include higher plasma glucose (>600 mg/dL), a lack of acidosis ($\text{pH} > 7.3$, $\text{CO}_2 > 18$ mEq/L), more profound dehydration (serum osmolality > 320 mOsm/kg), and a change in mental status.⁹ Patients with HHS often have low levels of ketones (β -hydroxybutyrate between 0.3 and 3.0 mmol/L) compared with DKA patients, whose β -hydroxybutyrate levels will be greater than 3.0 mmol/L.

Initial laboratory studies should include electrolytes, phosphorus, blood urea nitrogen (BUN), creatinine, urinalysis, complete blood count with differential, and electrocardiogram (see Table 58.2). Further evaluation should be undertaken based on the patient's presentation. A variety of laboratory abnormalities are frequently seen in DKA. Amylase, from both salivary and pancreatic sources, may be increased in up to 90% of patients with DKA. Lipase, normally a sensitive marker for pancreatitis, may also be elevated in DKA. However, the clinician should be aware that 10% to 15% of DKA patients do have concomitant pancreatitis.^{41,42} Leukocytosis of 10,000 to 15,000 white blood cells/mm³ is common, but levels greater than 25,000 cells/mm³ or the presence of greater than 10% band neutrophils should increase the clinical suspicion for an active infection. Elevated hemoglobin due to the volume depletion may be present. High liver function studies occur commonly, especially in patients with fatty liver;⁴³ and mild increases in creatine kinase and troponin may occur in the absence of myocardial damage.⁴⁴

Intercurrent illnesses contribute to the morbidity and mortality rates in a hyperglycemic emergency, and every patient with DKA or HHS should undergo a thorough assessment with a focus on infectious and cardiovascular causes.³⁴ Appropriate management should be started immediately and continue concurrent to the treatment of the DKA and HHS.

Additional causes of acidosis or ketosis should be considered in the differential diagnosis including starvation ketosis; alcoholic ketoacidosis; lactic acidosis; intoxication from methanol, salicylate, or ethylene glycol; chronic renal failure; and rhabdomyolysis.³⁴

MANAGEMENT

The treatment of HHS and DKA in adults and children follows similar principles of intravenous (IV) fluid, insulin, and electrolyte management. Children require more attention to weight-based regimens for fluid management in order to avoid cerebral edema.⁴⁵ The details of the management of HHS and DKA in patients older than 20 years are detailed in Figure 58.2.

FLUID REPLACEMENT

Although hyperglycemia drives the cascade of osmotic diuresis, volume depletion, and renal insufficiency, the process is reversed with appropriate fluid replacement.⁴⁶ In both DKA and HHS, normal saline solution should be started at 15 to 20 mL/kg body weight per hour initially (maximum of 1 L/hour), with hourly assessments of fluid status and urine output.⁴⁶ The infusion rate can be lowered to 250 to 500 mL/hour once the blood pressure stabilizes.

Once the sodium corrects to the eunatremic or hypernatremic level the fluids should be changed to one half normal saline solutions. Fluid rates are titrated based on the response to treatment and volume status. Patients with congestive heart failure (CHF), an acute myocardial infarction (MI), evidence of volume overload, or anuria warrant less aggressive fluid replacement and close monitoring of volume status. To avoid hypoglycemia, dextrose should be added to the IV fluids once the glucose drops below 250 mg/dL. Addition of dextrose to the IV fluid allows for the continued infusion of insulin that is necessary for the correction of ketoacidosis in DKA.

INSULIN

An initial bolus of regular insulin is typically given at 0.1 to 0.15 units/kg body weight followed by an IV insulin infusion at 0.1 unit/hour, though there is little evidence to support the need for an initial bolus.^{47,48} Higher dose insulin regimens are not beneficial.^{49,50} In patients receiving IV insulin, point of care testing should be performed every 1 to 2 hours and may be changed to every 2 hours once the patient is stable. Although subcutaneous (SC) and intramuscular (IM) insulin protocols can treat DKA or HHS, the initial response to glucose lowering is slower, and SC or IM regimens are generally reserved for emergent situations (i.e., a DKA patient with severe hyperkalemia and electrocardiographic [ECG] changes) in which IV access has been delayed.^{49,51}

With the initial correction of volume depletion, particularly in HHS, the glucose level may fall precipitously. Thereafter, glucose levels should make a steady decline of 50 to 75 mg/dL each hour.³⁴ There is no advantage to a more rapid improvement in the glucose level. The rate of insulin infusion may be adjusted to allow the glucose to trend downward at an appropriate rate. Once the glucose level decreases to less than 250 mg/dL, dextrose is added to the IV fluid to allow for the continued insulin infusion necessary to resolve the acidosis, because the fall in glucose will precede normalization of the acid-base status.⁹ By this point, the insulin infusion rate will usually have been adjusted to 0.02 to 0.05 unit/hour.

Complete initial evaluation. Check capillary glucose and serum/urine ketones to confirm hyperglycemia and ketonemia/ketonuria. Obtain blood for metabolic profile. Start IV fluids: 1.0 L of 0.9% NaCl per hour.[†]

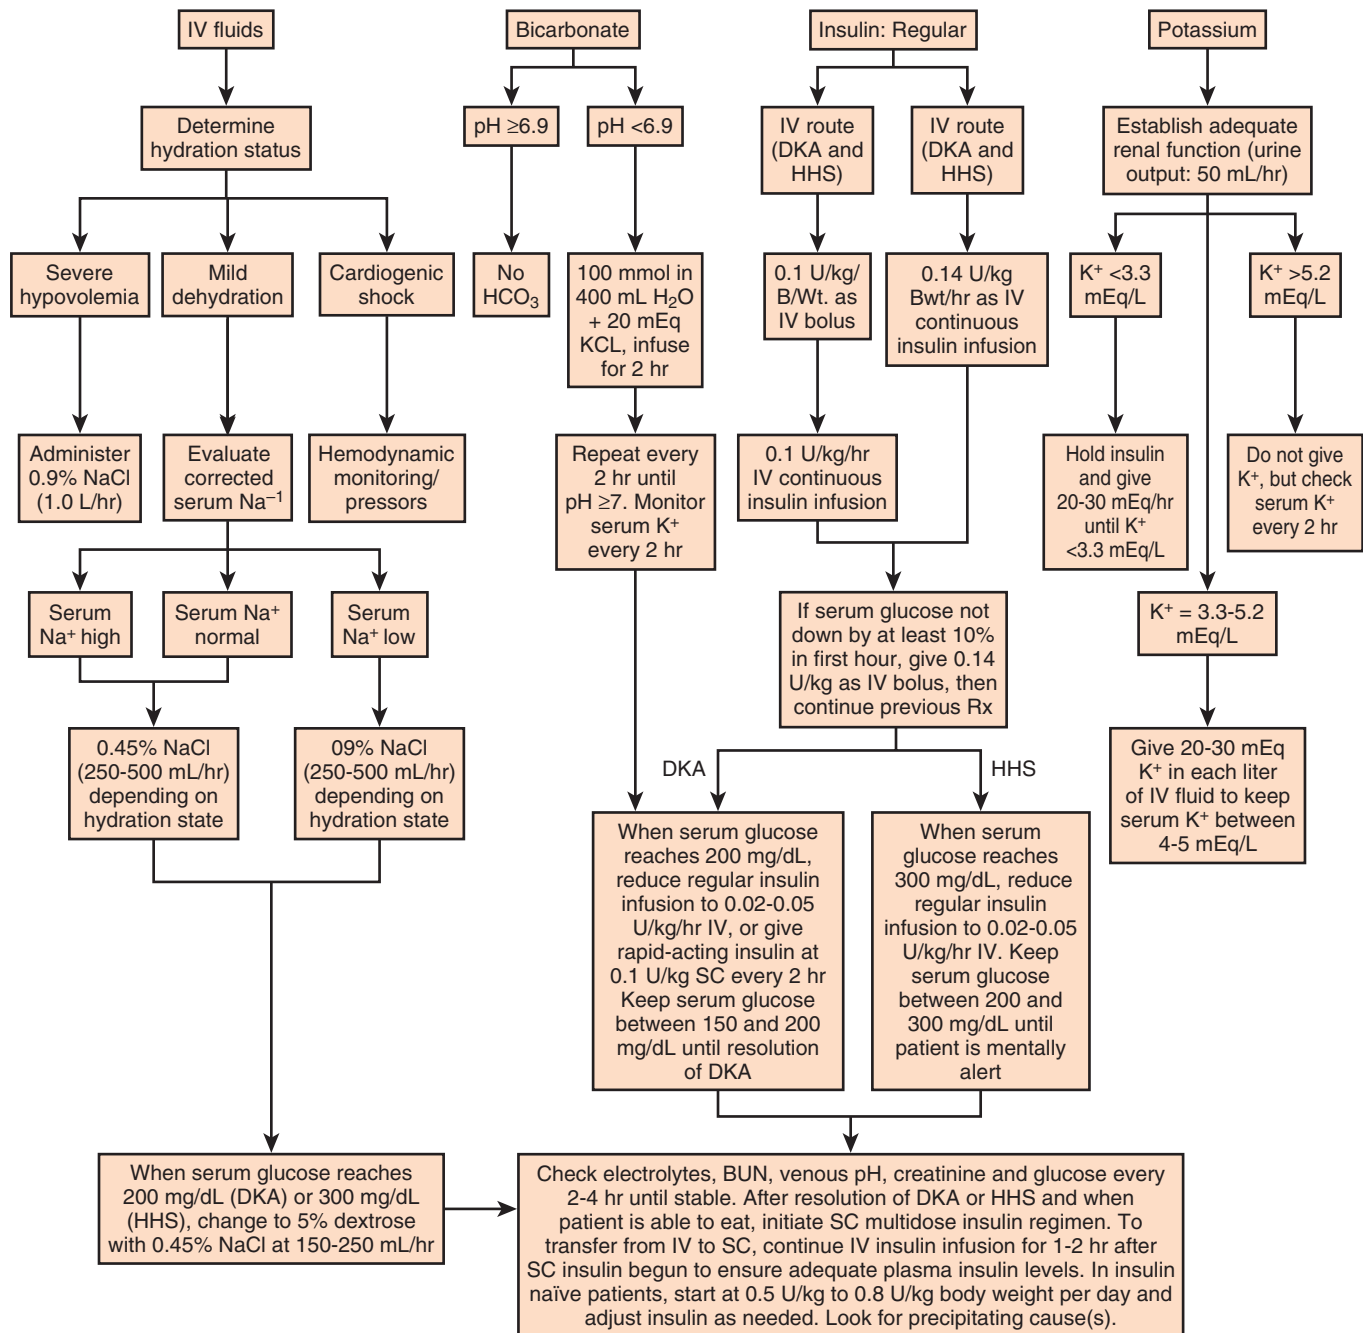

Figure 58.2 Protocol for the management of adult patients with diabetic ketoacidosis (DKA) or hyperglycemic hyperosmolar state (HHS). DKA diagnostic criteria: blood glucose 250 mg/dL, arterial pH 7.3, bicarbonate 15 mEq/L, and moderate ketonuria or ketonemia. HHS diagnostic criteria: serum glucose greater than 600 mg/dL, arterial pH greater than 7.3, serum bicarbonate greater than 15 mEq/L, and minimal ketonuria and ketonemia. [†]15 to 20 mL/kg/hour; [‡]serum Na should be corrected for hyperglycemia (for each 100 mg/dL glucose, add 1.6 mEq to sodium value for corrected serum value). Bwt, body weight; IV, intravenous; SC, subcutaneous. (From Kitabchi AE, Umpierrez GE, Miles JM, Fisher JN: Hyperglycemic crises in adult patients with diabetes. *Diabetes Care* 2009;32(7):1335-1343.)

The insulin infusion should be continued until resolution of the hyperglycemic crisis. In DKA, resolution of ketoacidosis is indicated by a normalization of the anion gap or a drop in the β -hydroxybutyrate level to less than 3 mmol/L.⁵² In HHS, resolution is indicated by correction of the fluid and electrolyte abnormalities. Once the acute abnormalities

have resolved and the glucose level has improved to less than 200 mg/dL, the patient can be transitioned to scheduled SC insulin. Patients should be placed on a physiologic insulin regimen, which includes a basal insulin (NPH, glargine, or detemir) and a mealtime, or “nutritional,” insulin (regular, lispro, aspart, or glulisine). NPH and

regular insulin are associated with higher rates of hypoglycemia.⁵³ The use of corrective (“sliding scale”) insulin as the sole SC insulin strategy is never appropriate in a patient recovering from DKA. Most protocols call for 80% to 100% of the calculated daily insulin requirements to be started based on a stable insulin infusion.⁵⁴⁻⁵⁷ The insulin doses are divided into 50% basal and 50% nutritional insulin.

Older age, higher IV insulin requirements, and greater blood glucose variation decrease the chance of a successful transition.⁵⁶ Other potential pitfalls include discontinuing the IV insulin without initiating physiologic insulin, and over- or underestimating the 24-hour insulin requirements based on fluctuating insulin infusion rates. Despite pressures in a busy intensive care unit (ICU) to transition patients off IV insulin, the SC insulin needs to be calculated based on the relatively stable IV insulin requirements over 4 to 6 hours prior to the transition.⁵⁷ IV insulin should not be discontinued until at least 2 hours after the start of basal insulin. A protocol for the successful transition from IV to SC insulin is listed in [Box 58.2](#).⁵⁸

POTASSIUM

Patients with DKA or HHS may initially present with hyperkalemia or hypokalemia, each with significant potential cardiac consequences. Tall peaked T waves in the precordial

leads are the first ECG sign of hyperkalemia as the potassium increases above 5.5 mmol/L. As potassium levels increase to greater than 6.5 mmol/L, additional ECG changes emerge: prolonged PR interval, decreased amplitude of P waves, and a widening of the QRS complex. As the potassium increases to greater than 8.0 mmol/L more ominous changes occur, including loss of P waves; intraventricular, fascicular, and bundle branch blocks; and widening of the QRS complex, ultimately resulting in asystole.⁵⁹ Conversely, hypokalemia also increases the risk of cardiac arrhythmia. ECG changes in hypokalemia include broad flat T waves, ST-segment depression, and QT interval prolongation.⁶⁰ Additionally, hypokalemia decreases myocardial contractility.⁶⁰

Treatment with volume expansion and insulin will lower serum potassium levels as potassium shifts from the extracellular to intracellular space. Electrolytes should be monitored every 2 to 4 hours in the early stages of DKA.^{9,32} For a potassium concentration greater than 5 mmol/L, serum K⁺ testing should be repeated every 1 to 2 hours. Potassium replacement should be started once the potassium decreases into the normal range and the patient is producing urine. Once serum potassium is below 5 mmol/L, patients should receive KCl 5 mEq/hour via the IV fluid, and the rate can be increased to 10 mEq/hour if the serum K⁺ is below

Box 58.2 Important Steps in Transition from Insulin Infusion to Subcutaneous (SC) Insulin

Step 1: Is the patient stable enough for transition?

Hypotension, active sepsis, use of pressors, and intubation are contraindications to transition because these factors are recognized to be associated with unreliable subcutaneous insulin absorption, with continued need for the most flexible dosing due to frequently changing insulin requirements.

Step 2: Does the patient need to switch to scheduled SC insulin?

Yes:

Type 1 DM—all patients
Type 2 DM in patients on home insulin regimen
Type 2 DM in patients with a recent mean infusion rate ≥ 0.5 unit/hour

No:

Type 2 DM in patients with a recent mean infusion rate < 0.5 unit/hour
Stress hyperglycemia or previously unrecognized DM if infusion rate < 1 unit/hour or if HbA_{1c} is near normal

Step 3: If transition is needed, calculate a total daily dose (TDD) of insulin. The TDD is an estimate of the 24-hour insulin requirement when the patient is receiving full nutrition.

- Determine mean insulin infusion rate from last 6-8 hours.
- Calculate 24-hour insulin dose based on this rate, and reduce the 24-hour dose by 20%.
 - Multiply hourly insulin infusion rate by 20 (80% of 24) to arrive at a safety-adjusted 24-hour insulin dose.
- Determine if this total is the TDD or basal dose based on current nutrition.
 - If the infusion was providing both the basal and nutritional needs of the patient (i.e., continuous tube feeds), this will be the TDD.

OR

- If the infusion was not covering significant nutrition, this *could* be the basal insulin dose.

Step 4: Construct a basal/bolus regimen tailored to the patient's nutritional situation, building safeguards for any changes in nutritional intake and uncertainties about reliability of intake. Several options are again available.

- **Basal:** glargine, detemir, or NPH

1. Dose is 40-50% of TDD.

OR

2. Adjusted 24-hour intravenous requirement can be given as all basal.

- **Nutritional:** The remainder of TDD is scheduled nutritional insulin in divided doses. In general, these doses need to be adjusted down for $< 100\%$ nutritional intake, and the orders should allow for administering nutritional insulin just AFTER observed meal to allow an assessment of intake. Several options are available for estimating the initial doses:

1. Use 50% of the TDD as nutritional coverage, and divide this amount by 3 to determine the scheduled meal dose. Hold if patient does not eat more than 50% of each meal.
2. Use a more conservative start of $0.1-0.2 \times$ basal dose for each meal.
3. Use carbohydrate counting to cover nutritional intake.

Step 5: Be sure to give SC insulin BEFORE the infusion stops.

- Basal glargine and detemir ideally are given at least 2 hours before infusion is discontinued.
- Shorter lead times (30 minutes) are possible if rapid-acting insulin is given with basal insulin.

DM, diabetes mellitus; HbA_{1c}, hemoglobin A_{1c} (glycosylated hemoglobin).

Modified from O'Malley CW, Emanuele M, Halasyamani L, Amin AN. Bridge over troubled waters: safe and effective transitions of the inpatient with hyperglycemia. *J Hosp Med* 2008, 3(S5):S55-65.

4 mmol/L. Lower doses should be used if the patient has evidence of impaired renal function.

BICARBONATE

The metabolic acidosis of DKA impairs myocardial contractility, affects oxyhemoglobin dissociation and tissue oxygen delivery, inhibits intracellular enzymes, alters cellular metabolism, and may result in vital organ dysfunction.⁶¹ Correction of acidosis focuses on the correction of insulin deficiency and volume depletion, as well as any other underlying conditions that may be contributing to the acidosis. Although the administration of bicarbonate would appear to be a reasonable consideration, multiple trials of bicarbonate replacement in DKA patients have demonstrated no benefit.^{61,62} Furthermore, the use of IV bicarbonate may result in complications.^{34,40} Bicarbonate therapy has been associated with hypokalemia, intracellular acidosis, and tissue hypoxia.⁴⁷ On the other hand, a potential benefit for bicarbonate therapy in those individuals with severe acidemia (pH < 6.9)^{62,63} has been suggested, though the literature is limited. In patients with pH less than 6.9, the use of sodium bicarbonate (100 mmol sodium bicarbonate in 400 mL sterile water with 20 mEq KCl, administered at a rate of 200 mL/hour for 2 hours, and then repeating every 2 hours) may be considered until the pH is greater than 6.9.⁹

PHOSPHATE

Phosphate levels initially may be normal to elevated, but usually decline with treatment.⁶⁴ There is no evidence to support the routine use of phosphate replacement in patients with DKA.^{65,66} Nevertheless, severe hypophosphatemia may impair oxygen delivery and cause muscle fatigue, and selective replacement is suggested in patients with phosphate levels less than 1.0 mg/dL, anemia, respiratory failure, or CHF.^{9,67} Correcting the phosphorus level improves tissue oxygenation and restores the body's buffering capacity. Phosphate is generally replaced as a potassium salt.⁶⁸ To avoid complications, particularly hypocalcemia, phosphorus replacement should be limited to 40 to 50 mmol of potassium phosphate at approximately 3 to 4 mmol/hour. The potassium being provided in other IV fluids may need to be adjusted to account for the potassium infused as part of the phosphorus replacement.⁶⁸

HYPERCHLOREMIC ACIDOSIS

The development of hyperchloremic acidosis occurs in DKA because the ability to completely regenerate bicarbonate is hampered by the urinary loss of keto acids, which normally act as substrate for the re-formation of bicarbonate. To maintain the appropriate balance of cations and anions, chloride ions from the infused saline will partially compensate for the lack of bicarbonate. As the ketoacidosis resolves, a hyperchloremic acidosis (with a normal anion gap) may ensue. This benign process resolves gradually in the hours to days after the saline infusion is reduced or stopped.⁶⁸

COMPLICATIONS OF THE MANAGEMENT OF HYPERGLYCEMIC EMERGENCIES

Management of hyperglycemic emergencies is associated with several complications, the most common being

iatrogenic hypoglycemia from aggressive insulin dosing. Frequent monitoring of glucose (every 1-2 hours) and down-titration of insulin doses as the glucose approaches normal are appropriate strategies to prevent hypoglycemia. The addition of dextrose-containing IV fluid is suggested when the glucose level drops below 250 mg/dL to allow for the continued insulin infusion necessary to restore the acid-base balance.

Cerebral edema is the one of the most feared complications of hyperglycemic crisis. Classically, cerebral edema has been reported in children with DKA. It occurs in 0.5% to 1% of all DKA cases^{69,70} and carries a mortality rate of 20%. Survivors are at risk for residual neurologic problems.⁴⁵ Although cerebral edema is occasionally seen in adults with HHS, it is rare in adults with DKA and children with HHS.⁷¹ Children who present with (1) low partial pressures of arterial carbon dioxide and (2) high serum urea nitrogen concentrations and (3) are treated with bicarbonate are at increased risk for cerebral edema. The exact cause of cerebral edema remains unknown. It does not appear to be associated with the initial level of hyperosmolarity or more rapid correction of the hyperosmolarity.^{72,73} Cerebral ischemia, and not changes in osmolality, may be the causal factor in patients who develop cerebral edema.⁷³ Nevertheless, care should be taken to avoid rapid changes in glucose and osmolality, especially in younger patients. The clinician should also be aware of the signs of cerebral edema, which include headache, persistent vomiting, hypertension, bradycardia, and neurologic changes.

Attention to the diagnosis and management of any infections or cardiovascular events is imperative. Other complications of the management of DKA and HHS include hypokalemia, hypophosphatemia, acute renal failure, and shock. Appropriate management of hyperglycemic emergencies with close attention to fluid and electrolyte balance minimizes these complications. Less common problems can include rhabdomyolysis,⁷⁴ thrombosis and stroke,⁷⁵ pneumomediastinum,⁷⁶ and memory loss with decreased cognitive function in children.⁷⁷

PREVENTION

Despite improvements in insulin treatment and glucose monitoring,⁷⁸ the incidence of DKA is increasing.³ Prevention is paramount. Health care providers should recognize signs of DM in all age groups. Patients with DM and their caregivers should be familiar with sick day recommendations (Box 58.3), and patients with type 1 DM should check urine ketones by dipstick if the glucose is greater than 240 mg/dL.⁷⁹ Home measurement of serum ketones with a commercial glucometer may allow earlier detection of DKA and decreased hospital visits,⁸⁰ though most meters lack this capability.

Nonadherence to medical regimens is often cited as the cause of recurrent DKA, and in fact, 5% of patients account for more than 25% of all cases of DKA.⁸¹ Health care providers need to recognize disparities in the health care system that limit access to appropriate DM care or otherwise contribute to nonadherence with insulin or other antidiabetic medications. Diabetes education enhances patient knowledge of appropriate monitoring and prevention of DKA,⁸² and diabetes educators are an excellent resource to help

Box 58.3 Sick Day Management Protocol for Diabetic Patients^{212,213}

Examples of “Sick Day” Scenarios

- Feeling sick or presence of fever for 2 days or longer without getting better
- Vomiting or diarrhea for more than 6 hours

Management

General Measures

- Check blood sugar levels at least every 4 hours, but when values are changing quickly, check more often.
- Check urine or blood ketones.
- Modify usual insulin regimen according to a plan developed by the diabetes physician or team.
- Maintain adequate food and fluid intake. If your appetite is poor, aim for consumption of 50 g of carbohydrate every 3-4 hours. If you are nauseous, high-carbohydrate liquids, such as regular (not diet) soft drinks or juice, or frozen juice bars, sherbet, pudding, creamed soups, or fruit-flavored yogurt usually are tolerated. Broth also is a good alternative.

Taking Medications When You Are Sick

- If you are eating: Continue taking your pills for diabetes or your insulin. Your blood sugar may continue to rise because of your illness.
- If you are nauseous or vomiting or otherwise cannot take your medicines:
 - Continue to take your long-acting insulin (Lantus, Levemir, NPH).
 - Call your doctor and discuss whether you need to adjust your short- or rapid-acting insulin dose (regular, lispro [Humalog], aspart [Novolog], glulisine [Apidra]) or your other diabetes medicines.

Examples of When to Call Physician or Diabetes Team

- If glucose levels are higher than 240 mg/dL despite taking extra insulin according to a sick day plan
- If you take diabetes pills and blood sugar is still above 240 mg/dL before meals and remains there for more than 24 hours
- If symptoms/signs develop that might signal DKA or dehydration, such as dizziness, trouble breathing, fruity breath, or dry and cracked lips or tongue

DKA, diabetic ketoacidosis.

assess a patient's barriers to optimal care including financial, social, and cultural issues.⁸²

GLYCEMIC CONTROL IN THE INTENSIVE CARE UNIT

EPIDEMIOLOGY AND SIGNIFICANCE OF HYPERGLYCEMIA

Hyperglycemia is a common occurrence in hospitalized patients and is associated with increased morbidity and mortality rates,⁸³⁻⁸⁵ including higher rates of surgical infections

after cardiothoracic surgery,^{86,87} increased mortality rates after MI,⁸⁸⁻⁹⁰ and poor outcome in critically ill patients.^{91,92} Forty percent of patients in the ICU and 80% of those undergoing cardiac surgery have elevated glucose levels.⁹³ Of hyperglycemic patients in the hospital, two thirds have a history of diabetes, although the remainder have no prior history.⁸⁵ This latter group includes patients with previously unrecognized diabetes as well as those with “stress hyperglycemia” (patients who are normoglycemic on follow-up testing). Only 15% of patients with new-onset hyperglycemia have confirmed diabetes 1 year after the hospital admission.⁹⁴ Hyperglycemic patients with no prior history of diabetes have a worse prognosis than patients with preexisting diabetes, including greater mortality rates after MI⁸³ and a significantly increased 30-day and 1-year mortality rate.⁹⁵ This is particularly true of patients with stress hyperglycemia, a condition of acutely elevated glucose related to illness-related increases in counterregulatory hormones seen (Fig. 58.3)⁹³ in patients with otherwise normal glucose metabolism. Stress hyperglycemia is consistently associated with increased adjusted mortality rates for patients with unstable angina, acute MI, CHF, arrhythmia, ischemic and hemorrhagic stroke, gastrointestinal bleeding, acute renal failure, pneumonia, pulmonary embolism, and sepsis.⁹⁶

Glucose variability, measured as the standard deviation of glucose excursions around the mean, adds to the metabolic burden.⁹⁷ Glycemic variability may be a better predictor of morbidity and mortality rates than the level of hyperglycemia in patients with preexisting diabetes.⁹⁸⁻¹⁰⁰ In a retrospective analysis, the odds ratio for ICU death is significantly greater in patients with higher hourly change in glucose.¹⁰¹ Glycemic variability may be a better predictor of morbidity and mortality rates than the level of hyperglycemia in patients with preexisting diabetes.⁹⁸⁻¹⁰⁰

SYNOPSIS OF TRIALS OF GLYCEMIC CONTROL

The benefits of improved glucose control were initially suggested by several retrospective or nonrandomized trials in patients with acute MI,¹⁰² with stroke,⁸⁴ after coronary artery bypass surgery,⁸⁷ and in the ICU.¹⁰³ A landmark single-center prospective study in surgical ICU patients was published in 2001, in which intensive insulin therapy (IIT) was reported to decrease ICU and in-hospital mortality rates, as well as significant comorbid conditions such as bloodstream infections, acute renal failure requiring dialysis or hemofiltration, the median number of red blood cell transfusions, critical-illness polyneuropathy, and prolonged mechanical ventilation. The number of patients who received red-cell transfusions did not differ significantly between the two groups. However, the median number of transfusions in the intensive-treatment group was only half that in the conventional-treatment group. This difference was not due to more liberal use of transfusions in the conventional-treatment group, as indicated by the lower hemoglobin and hematocrit values in that group.¹⁰⁴ Based on this study, many ICUs initiated IV insulin protocols designed to achieve glucose levels in the 70- to 110-mg/dL range. Soon, however, enthusiasm over the benefits of normoglycemia from IIT in the critically ill patient were tempered by (1) an inability to extend the initial results across multiple centers,^{105,106} (2) concern over the risk of hypoglycemia,^{105,106} (3) questions

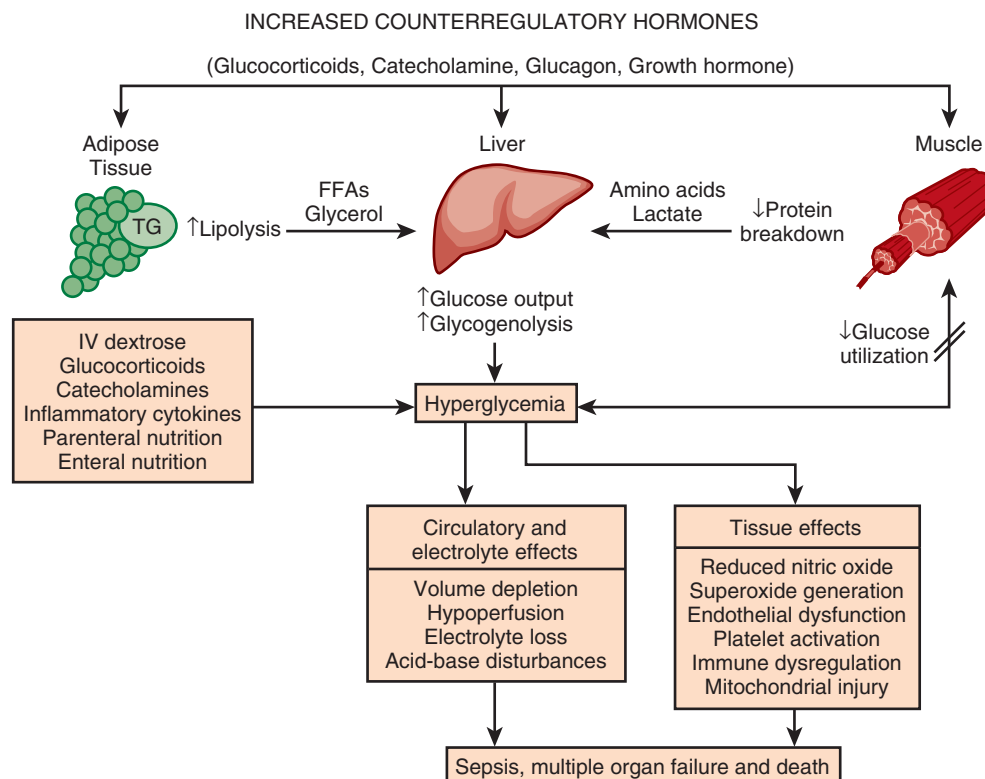

Figure 58.3 Pathogenesis of stress hyperglycemia. Stress hyperglycemia results from increased hepatic glucose production and impaired glucose utilization in peripheral tissues. Excess counterregulatory hormones (glucagon, cortisol, catecholamines, and growth hormone) increase lipolysis and protein breakdown (proteolysis), and impair glucose utilization by peripheral tissues. Hyperglycemia causes osmotic diuresis that leads to hypovolemia, decreased glomerular filtration rate, and worsening hyperglycemia. At the cellular level increased blood glucose levels result in mitochondrial injury by generating reactive oxygen species and endothelial dysfunction by inhibiting nitric oxide production. Hyperglycemia increases levels of proinflammatory cytokines such as tumor necrosis factor- α (TNF- α), and interleukin 6 (IL-6), leading to immune system dysfunction, and increases plasminogen activator inhibitor-1 and fibrinogen, causing platelet aggregation and hypercoagulable state. These changes can eventually lead to increased risk of infection, impaired wound healing, multiple organ failure, prolonged hospital stay, and death. (From Farrokhi F, Smiley D, Umpierrez GE: Glycemic control in non-diabetic critically ill patients. *Best Pract Res Clin Endocrinol Metab* 2011;25:813-824.)

over the role of early nutrition,¹⁰⁴ and (4) a less pronounced improvement for patients with preexisting diabetes.¹⁰⁷ Additionally, nonrandomized and observational studies suggested a J-shaped curve for mortality rate related to glycemic control in the ICU with increasing mortality rate for glucose levels less than 90 mg/dL and greater than 120 mg/dL.^{96,103,108-110} In the NICE-SUGAR (Normoglycemia in Intensive Care Evaluation—Survival Using Glucose Algorithm Regulation) study,¹¹¹ a randomized controlled, multicenter trial, in which ICU patients were randomized to intensive glycemic control or conventional glucose control, no mortality rate benefit was seen with IIT. In a meta-analysis of studies evaluating the impact of intensive glycemic control, including the results from NICE-SUGAR, the relative risk of death was not significantly different with IIT compared with conventional therapy, but the risk of severe hypoglycemia was significantly greater.¹¹² Figure 58.4 summarizes key studies on the impact of intensive glycemic control.

The foremost obstacle to the use of IIT is hypoglycemia. Patients managed with IIT for tight glycemic control have significantly greater rates and duration of hypoglycemia.^{112,113} Hypoglycemia from insulin therapy increases mortality risks in critically ill patients,^{105,114-118} which may mitigate any benefits of tight glucose control.¹⁰⁴ As expected, use of glucose control algorithms modified for a higher

glucose target range significantly reduces the risk of severe hypoglycemia.^{119,120}

INTRAVENOUS INSULIN PROTOCOLS

A standardized insulin protocol should be used to maintain goal glucose levels and reduce hypoglycemic episodes. Current practice requires the clinician to consider the multiple factors affecting glucose control, such as changes in nutrition, medication or medical acuity, and proactively respond to avoid large fluctuations in glucose levels. An effective IV insulin protocol allows for titration of IV insulin in the setting of changing glucose levels. Multiple published insulin protocols are available,^{54,57,121-126} though any protocol will need to be adapted and adjusted to fit the needs of the local environment. A multidisciplinary team consisting of intensivists, endocrinologists, nurses, and pharmacologists should be involved in the development, implementation, and continued evaluation of IV insulin protocols.

TECHNICAL ISSUES IN MEASURING GLUCOSE

Accurate measurement of glucose in the ICU is essential to maintain glycemic control and limit the risk of severe hypoglycemia. The use of IIT magnified the importance of

accurate point of care (POC) glucose monitoring. In the ICU measurements of glucose are affected by the clinical status of the patient, by certain medications, and by the type of blood sample.¹²⁷ Anemia may falsely elevate POC glucose levels, which can mask hypoglycemia.¹²⁸⁻¹³⁰ This deserves attention given the high prevalence of anemia routinely encountered in ICUs.¹³¹ The accuracy of POC testing is also affected by several other common conditions (e.g., acidosis, hypothermia, and hypotension) and medications (dopamine, mannitol, acetaminophen, and pressor use).¹³²⁻¹³⁵ The rates of inpatient variability in glucose measurements are lowest from arterial samples. Variability increases in venous sampling with the greatest variability in capillary blood. Arterial blood analysis correlates better with central laboratory glucose values than capillary blood measurements. During hypoglycemia, the discrepancy is exaggerated. POC capillary and whole blood samples from patients with poor peripheral perfusion overestimate the laboratory glucose level by 20% in a significant proportion of samples.¹³⁶ The difference between capillary and arterial blood glucose measurements has led most insulin protocols for ICUs to recommend the use of arterial blood measurements when available.¹³⁶

Subcutaneous electrochemical sensors can measure glucose levels in the interstitial fluid and report an average glucose level every 1 to 10 minutes, although a lag time of 8 to 18 minutes exists between blood glucose and interstitial glucose equilibration.¹³⁷ Determining trends in glucose, the devices may provide earlier detection of hypoglycemia and hyperglycemia. Several small studies found excellent accuracy for continuous glucose monitoring (CGM) in the ICU as compared to POC testing.¹³⁷⁻¹⁴⁰ However, there is currently insufficient evidence to support the general use of CGM in the ICU.¹⁴¹

CURRENT GUIDELINES FOR GLYCEMIC CONTROL

The current guidelines for glycemic control in the ICU have transitioned from declarations for tight glycemic control (based on observational and retrospective data and a single-site randomized controlled study) to more moderated goals taking into account the increased mortality rate associated with hypoglycemia and the limited benefit from tight glycemic control seen in other trials.^{105,106,142,143}

The 2009 American Academy of Clinical Endocrinologists and American Diabetes Association Consensus Statement on Inpatient Glycemic Control¹²² recommends insulin therapy for persistent hyperglycemia at a threshold no greater than 180 mg/dL, with a target range for glucose levels in the ICU of 140 to 180 mg/dL. The guideline recommends treatment with IV insulin using an established protocol associated with low rates of hypoglycemia and frequent glucose monitoring.

The 2012 Surviving Sepsis Guidelines (2012)¹⁴⁴ recommend:

- Initiating an IV insulin protocol in ICU patients with severe sepsis who have two consecutive blood glucose levels greater than 180 mg/dL
- Targeting a blood glucose level less than 180 mg/dL
- Providing a glucose calorie source to all patients on IV insulin

- Monitoring glucose levels every 1 to 2 hours until infusion rates are stable, then every 4 hours
- Interpreting POC capillary blood glucose testing with caution, keeping in mind that this may overestimate arterial blood glucose or plasma glucose

THE EFFECT OF PARENTERAL NUTRITION, ENTERAL NUTRITION, AND GLUCOCORTICOIDS ON GLYCEMIC CONTROL

Changes in nutrition and glucocorticoid dosing occur commonly, often quickly, in the intensively ill patient. Even when changes in enteral or parenteral nutrition are planned, or the patient is on a prescribed steroid taper, insulin adjustments need to be considered proactively to minimize glycemic variability.

Enteral feeding preparations have high concentrations of carbohydrates, and are associated with an increase in glucose concentration.^{145,146} Similarly, the majority of patients with type 2 DM who are not on insulin prior to ICU admission require insulin to maintain glycemic control once parenteral nutrition is initiated.¹⁴⁷ It is advisable to begin an IV or SC insulin regimen at the onset of total parenteral nutrition/peripheral parenteral nutrition (TPN/PPN) use,¹²² or alternatively, regular insulin can be added to parenteral nutrition. When nutrition is held or discontinued, the insulin dosing will usually need to be reduced, or dextrose-containing IV fluid started, to reduce the risk of hypoglycemia.

Glucocorticoid-induced hyperglycemia is common in the critically ill patient. Glucocorticoids decrease insulin sensitivity, impair glucose disposal, and increase hepatic insulin resistance.¹⁴⁸ All patients should have regularly scheduled glucose monitoring for the first 48 hours after steroids are initiated. Subcutaneous insulin therapy may be started for glucocorticoid-induced hyperglycemia with an initial total daily dose (TDD) of 0.3 to 0.5 unit per kg body weight. IV insulin infusion is appropriate for moderate to severe hyperglycemia.¹⁴⁹ In patients started on insulin for glucocorticoid-induced hyperglycemia, the insulin dose will need to be titrated for changes in steroid dose.

SUBCUTANEOUS INSULIN USE IN THE HOSPITALIZED PATIENT

Insulin is the therapy of choice for glucose control in the ICU. Oral agents and noninsulin injectable agents should be discontinued on admission. The multiple contraindications and the inability to make rapid adjustments for changes in clinical or nutritional status make noninsulin therapy poorly suited for the care of the critically ill patient. The onset, peak, and duration of action of the currently available insulin preparations are listed in (Table 58.3). Insulin can be categorized based on the physiologic profile: basal insulin is either long or intermediate duration; short- or rapid-acting insulin is used for prandial control and for the correction of hyperglycemia. The lack of a defined peak and prolonged action profile make glargine (Lantus) and detemir (Levemir) advantageous for use as a basal insulin. Glargine is typically dosed once daily and detemir one to two times daily. NPH has an intermediate duration of action

Table 58.3 Onset, Peak, and Duration of Action of Currently Available Insulin Preparations

Insulin Preparation	Onset of Action	Peak Action	Duration of Action
Lispro	5-15 min	30-90 min	3-5 hr
Aspart	5-15 min	30-90 min	3-5 hr
Glulisine	5-15 min	30-90 min	3-5 hr
Regular	30-60 min	2-3 hr	5-8 hr
NPH	2-4 hr	4-10 hr	12-20 hr
Detemir	2-4 hr	Relatively peakless	Up to 24 hr
Glargine	2-4 hr	Relatively peakless	20-24 hr

with peak effect at 6 to 8 hours after dosing and is usually dosed twice daily.

With a variety of insulin regimens available, the practitioner has several options available to manage hospitalized patients with diabetes or stress hyperglycemia. Patients who are not eating or who are receiving continuous nutrition (enteral or parenteral) should have a basal insulin in place. The basal insulin is given SC, or in the case of parenteral nutrition, regular insulin may be added to the PPN or TPN at an initial dose of 1 unit for each 15 g of dextrose.¹⁵⁰ In a patient on continuous nutrition or NPO (nothing by mouth), glargine is dosed daily, detemir every 12 to 24 hours, or NPH every 8 to 12 hours. No research is available to support the use of one basal insulin over another in the hospitalized patient. The potential risk of NPH is the peak effect, although the longer duration of glargine and detemir may result in longer periods of hypoglycemia. Glucose monitoring should be performed every 4 to 8 hours, depending on the stability of the patient.

In patients tolerating scheduled meals, a prandial insulin should be added. Lispro, aspart, and glulisine each have a more physiologic profile with a quicker onset of action, time to peak, and shorter duration of action than regular insulin. The use of a rapid-acting insulin analog is associated with better glycemic control compared to regular insulin.¹⁵¹ In patients who are eating, glucose monitoring is usually performed before the meal and at bedtime.

The lack of flexibility with premixed insulin (Humulin 70/30, Novolin 70/30, Novolog 70/30, and Humalog 75/25) makes their use less suitable for the hospital. Each of the premixed insulin preparations contains 70% to 75% NPH for intermediate-acting insulin and 25% to 30% of regular insulin or a rapid-acting insulin analog (lispro or aspart). Though not an optimal practice, if the practitioner wishes to continue a successful home regimen of premixed insulin in a hospitalized patient, the component doses of NPH and lispro, aspart, or regular insulin can be given separately.

In the hospitalized patient, there are several methods for determining insulin dosing for a basal-bolus regimen:

1. A weight-based protocol¹⁵² can be utilized, typically starting at 0.3 to 0.6 unit/kg body weight depending on the patient's weight and risk factors for insulin sensitivity

(body mass index [BMI] < 25, hepatic insufficiency, renal insufficiency) or insulin resistance (morbid obesity, sepsis, glucocorticoids). A weight-based regimen is helpful in initiating an SC insulin regimen in a patient with new-onset hyperglycemia or a patient who is on a noninsulin antidiabetic regimen with or without basal insulin. Fifty percent of the dose is given as basal insulin, and the remaining 50% is divided into three mealtime boluses.

2. The patient's home insulin basal-bolus dose can be restarted if the patient has good outpatient glucose control, based on a recent hemoglobin A_{1c} (HbA_{1c}) or a reliable history. The results of an HbA_{1c} obtained in the past 3 months will give insight into the efficacy of the patient's outpatient medical regimen, and may also help to determine if a patient without a history of diabetes has unrecognized DM versus stress hyperglycemia.
3. A premixed insulin regimen can be changed to basal-bolus by adding the TDD of insulin and then giving 50% as basal insulin and 50% as nutritional (mealtime) insulin.
4. An insulin regimen can be determined based on the IV insulin infusion requirements.

The use of correctional (sliding) scale insulin as sole therapy cannot be promoted for the patient with hyperglycemia. Reliance on sliding scale insulin is associated with worse glycemic control in hospitalized patients.^{153,154} In particular, patients with type 1 DM always require physiologic insulin dosing including a basal insulin to prevent the development of DKA. Correctional insulin doses may be used as an adjunct to a physiologic insulin regimen. Doses of correctional insulin should be aligned to the TDD of prescribed insulin; thus, a patient requiring 100 units of insulin a day will require more correctional dose insulin than a patient whose TDD is 30 units. The clinician can calculate the expected change in glucose for 1 unit of regular or rapid-acting insulin analog using the "Rule of 1500" formula: $1500/\text{TDD} = \text{expected decrease in glucose (in mg/dL) for 1 unit of correctional dose insulin}$. For insulin-sensitive patients (e.g., type 1 DM, BMI < 25 kg/m², end-stage renal disease [ESRD], or hepatic failure), 1800 rather than 1500 is used for the numerator.

HYPOGLYCEMIA

As noted in the previous section, hypoglycemia is the main deterrent to good glycemic control¹⁵⁵ and is associated with higher rates of morbidity and mortality in the ICU.^{105,120,156,157} Under normal circumstances the fasting glucose is 70 to 90 mg/dL.¹⁵⁸ Although only 1.5% of patients without DM or who are pre-DM will have clinically significant hypoglycemia,¹¹⁴ the critically ill patient is at enhanced risk of hypoglycemia due to underlying illness as well as the use of medications that can lower glucose.

PHYSIOLOGIC RESPONSE TO HYPOGLYCEMIA

The physiologic response to hypoglycemia is mediated through neural and humoral pathways and that involves both a reduction in insulin and activation of the

Figure 58.5 Physiologic and behavioral defenses against hypoglycemia in humans. α -cell, pancreatic islet alpha cells; ACh, acetylcholine; β -cell, pancreatic islet beta cells; NE, norepinephrine; PNS, parasympathetic nervous system; SNS, sympathetic nervous system; T1DM, type 1 diabetes. (From Cryer PE: Mechanisms of sympathoadrenal failure and hypoglycemia in diabetes. *J Clin Invest* 2006;116:1470-1473, used with permission of the American Society of Clinical Investigation.)

counterregulatory response¹⁵⁹ (Fig. 58.5). The first humoral response to a decreasing glucose is inhibition of insulin secretion when the glucose level drops to less than 80 mg/dL.^{159,160} The drop in insulin level causes decreased peripheral glucose utilization, as well as increased glucose production through glycogenolysis and gluconeogenesis.¹⁶¹ Glucagon, epinephrine, and growth hormone secretion increases as glucose levels fall below 70 mg/dL.^{159,160} Cortisol release increases as the glucose drops below 60 mg/dL. Of the counterregulatory hormones, glucagon plays the key role in the minute-to-minute prevention of hypoglycemia.¹⁶² If glucagon secretion is diminished (e.g., in longstanding autoimmune diabetes), epinephrine release becomes critical for the reversal of hypoglycemia. Under normal circumstances, cortisol and growth hormone are not essential in the prevention of hypoglycemia but are necessary in the absence of glucagon.¹⁵⁹ The stepwise response to hypoglycemia and the redundancy in the counterregulatory hormones suggest the physiologic importance placed on the prevention of hypoglycemia.¹⁵⁹

Table 58.4 Clinical Symptoms of Hypoglycemia

Sympathoadrenal	Neuroglycopenic
Tremor	Tiredness or drowsiness
Palpitations	Difficulty thinking
Diaphoresis	Confusion
Nervousness	Blurred vision
Anxiety or apprehension	Slurred speech
Hunger	Dizziness, weakness
Pallor	Abnormal or belligerent behavior
	Seizure
	Coma or death

SYMPTOMS

The symptoms of hypoglycemia can be thought of as either sympathoadrenal or neuroglycopenic (Table 58.4). The sympathoadrenal symptoms are mediated through both β - and α -adrenergic and cholinergic pathways, and begin as

the glucose decreases to less than 60 mg/dL.¹⁶³ These symptoms include cholinergic-mediated complaints of diaphoresis and hunger and adrenergic-related symptoms of tremulousness, palpitations, and anxiety.¹⁶³

Neuroglycopenic symptoms represent the effects of low glucose on the brain. Although the brain is responsible for 50% of the body's glucose use under physiologic conditions,^{164,165} it can neither generate glucose nor store glycogen. Thus, the brain requires a constant source of glucose.^{164,165} The onset of neuroglycopenic symptoms represents a drop in glucose below the critical level of glucose transport across the blood-brain barrier to meet the brain's metabolic demands.¹⁶⁶ Initial neuroglycopenic symptoms include the sensation of warmth, difficulty concentrating, weakness, fatigue, dizziness, difficulty speaking, and blurred vision.¹⁶³ As glucose falls, these effects may progress to confusion, behavioral change, lethargy, seizure, and coma. The severity of symptoms may be altered by the degree of hypoglycemia, the rate of fall in glucose levels, and the blunting of the hypoglycemic response from either medication or habituation from recurrent hypoglycemia.^{165,167}

HYPOGLYCEMIA IN PATIENTS WITH DIABETES OR WHO RECEIVE INSULIN

Although insulin is necessary to manage hyperglycemia in hospitalized patients, it is also the major risk factor for hypoglycemia. Additional risks for hypoglycemia are seen in (1) patients with comorbid conditions such as sepsis, organ failure, or malnutrition; (2) patients receiving medications such as beta blockers that mask the neurogenic symptoms of hypoglycemia; or (3) patients who do not have the capacity to respond to a hypoglycemic episode (e.g., sedated patients).

In patients with diabetes, hypoglycemia occurs with decreased or interrupted carbohydrate consumption, increased glucose utilization from elevated energy expenditure, or an increase in insulin to a degree that overwhelms the glucose counterregulatory system. The source of insulin may be exogenous, from an insulin injection or infusion, or endogenous, caused by an insulin secretagogue drug such as a sulfonylurea or a glinide. A detailed description of the onset, peak, and duration of the various types of insulin is given in the earlier section "Glycemic Control in the Intensive Care Unit." Sulfonylurea drugs such as chlorpropamide, tolbutamide, and glyburide, which have extended half-lives and are renally metabolized, predispose to prolonged hypoglycemia, particularly in patients with renal insufficiency.¹⁶⁸ Newer agents such as glipizide and glimepiride have dual hepatic and renal metabolism, which decreases the risk of prolonged hypoglycemia. The shorter duration of action of the glinides (repaglinide and nateglinide) reduce the risk of prolonged hypoglycemia. Diabetes medication affecting insulin resistance or carbohydrate consumption (i.e., metformin, thiazolidinediones, α -glucosidase inhibitors [AGIs], dipeptidyl peptidase IV inhibitors, amylin or incretin mimetics, bile acid sequestrants, or bromocriptine) do not typically cause clinically significant hypoglycemia unless taken in combination with insulin or an insulin secretagogue.

HYPOGLYCEMIC UNAWARENESS (HYPOGLYCEMIA-ASSOCIATED AUTONOMIC FAILURE)

Recurrent episodes of hypoglycemia,¹⁶⁹ particularly those that occur with sleep^{170,171} or exercise,^{172,173} blunt the normal response to hypoglycemia. This condition, known as hypoglycemia-associated autonomic failure (HAAF), reflects decreased adrenomedullary and sympathetic neural responses, and results in defective counterregulation and diminished symptoms of hypoglycemia, called hypoglycemic unawareness. The risk of severe hypoglycemia is markedly increased in patients with HAAF.¹⁷⁴ Furthermore, the response to glucagon and epinephrine may already be blunted in the critically ill patient,^{158,175} further increasing the hypoglycemic risk.

Over time, patients with type 1 diabetes develop diminished α -cell production of glucagon, leaving these patients at even higher risk of hypoglycemia. The inability of patients with type 1 DM to appropriately regulate insulin and glucagon secretion is associated with a 25 times greater risk of iatrogenic hypoglycemia. The absence of both β -cell (insulin) and α -cell (glucagon)¹⁷⁶ function also occurs following pancreatectomy and results in significant glycemic instability.¹⁷⁶

MANAGEMENT OF HYPOGLYCEMIA IN PATIENTS WITH DIABETES

A hypoglycemic patient with a history of diabetes should be evaluated for the frequency and severity of the hypoglycemic episodes, timing and dose of insulin or insulin secretagogues, missed or lower carbohydrate meals, increased physical activity, or new-onset hepatic or renal dysfunction. The risk of severe hypoglycemia increases with intensive glucose control.¹⁷⁷ Although an HbA_{1c} less than 7% can indicate excellent glucose control, it may also suggest an enhanced risk of hypoglycemia, particularly in the elderly.

Published protocols on the management of hypoglycemia are available.^{57,178,179} Patients who can eat should receive 15 to 20 g of carbohydrates with recheck of the glucose level in 15 to 20 minutes.¹⁸⁰ If the glucose remains less than 70 mg/dL,¹⁷⁸ the protocol should be repeated. A snack or small meal should follow once the hypoglycemic episode has resolved. Overtreatment with unmeasured carbohydrates such as fruit juice (with or without added sugar) increases the likelihood of rebound hyperglycemia and glycemic variability. Measured amounts of dextrose with glucose gel packets or glucose tablets offer more accurate dosing of carbohydrates. In the patient with IV access who is NPO or is unable to consume oral carbohydrates (including patients with impaired level of consciousness due to hypoglycemia), low glucose levels can be managed with 25 g of 50% dextrose (1 amp).¹⁵⁹ The use of glucagon should be limited to those patients with neuroglycopenic symptoms who have no IV access. The glycemic response to IV dextrose or glucagon may lead to moderate hyperglycemia.

It is important to be aware that in some instances (e.g., the use of long-acting insulin, or insulin secretagogues with long half-lives), there is increased risk that hypoglycemia will recur after initial treatment. The clinician needs to evaluate each episode of hypoglycemia for the underlying causes and adjust either the insulin dose, nutrition, or both.

Table 58.5 Risk Factors for Hypoglycemia in the Hospitalized Patient^{118,214}

Risk Factor	Prevention
Initiation of insulin	Individualized insulin dosing
Inappropriate timing of mealtime insulin	Mealtime insulin boluses up to 15 minutes before or 15 minutes after meal
Overuse or overdosing of correctional doses of insulin	Individualized insulin dosing based on total daily insulin requirements
Change in nutrition	Standardized orders to adjust insulin or add intravenous fluids with dextrose
Reduction in corticosteroid dose	Adjust insulin doses as steroid dose tapered

Superscript numbers refer to references provided online.

Other caveats exist in the management of hypoglycemia. First, glucagon induces glycogenolysis and thus is not effective in patients who are glycogen-depleted such as those with alcohol abuse. Second, although mild or moderate cases of hypoglycemia related to insulin secretagogues respond well to treatment with oral carbohydrates or dextrose, the recommended treatment of sulfonylurea overdose is octreotide 100 µg,¹⁸¹ which decreases the insulin secretion. Third, AGIs block the digestion of disaccharides, and therefore, treatment of hypoglycemia with disaccharides such as sucrose (cane sugar) or lactose (in milk) will be ineffective in patients taking AGIs. Oral glucose (dextrose), a monosaccharide, should be used.

PREVENTION

Forethought is required to prevent hypoglycemia in the ICU, but the prevention of hypoglycemia can be forgotten in the midst of multiple competing interests. Intensivists need to remain attentive to the increased risk for hypoglycemia as the patient's illness status, nutritional status, and medications change¹⁸² (Table 58.5). Particular attention should be given to the titration of insulin doses when steroids or epinephrine are being tapered.

A dependence on correctional dose insulin ("sliding scales") rather than scheduled basal-bolus insulin regimens has become endemic in many hospitals. This practice is to be strongly discouraged. The reliance on correctional insulin as the sole glycemic management strategy is associated with poor glycemic control and increased hypoglycemia, although a physiologic, basal-bolus insulin regimen improves glycemic control.⁵⁷

HYPOGLYCEMIA IN PATIENTS WITHOUT DIABETES

Because of the tiered physiologic mechanisms to protect against low blood glucose, hypoglycemia is unusual in nondiabetic patients. Only 1.5% of hypoglycemic episodes occur in patients without diabetes or who are not receiving insulin,¹⁶⁷ and most conditions or medications will not

Table 58.6 Causes of Hypoglycemia in Adults

Ill or Medicated Individual	Seemingly Well Individual
1. Drugs Insulin or insulin secretagogue Alcohol Others	1. Endogenous hyperinsulinism Insulinoma Functional cell disorders (nesidioblastosis)
2. Critical illnesses Hepatic, renal, or cardiac failure Sepsis (including malaria) Inanition	Noninsulinoma pancreatogenous hypoglycemia Post-gastric bypass hypoglycemia Insulin autoimmune hypoglycemia
3. Hormone deficiency Cortisol Glucagon and epinephrine (in insulin-deficient diabetes mellitus)	Antibody to insulin Antibody to insulin receptor Insulin secretagogue Other
4. Non-islet cell tumor	2. Accidental or malicious administration of antidiabetic agents

From Cryer PE, Axelrod L, Grossman AB, et al: Evaluation and management of adult hypoglycemic disorders: An Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab* 2009;94(3):709-728.

cause hypoglycemia unless multiple factors occur simultaneously.¹⁶⁷ The acute management of hypoglycemia is similar in diabetic and nondiabetic individuals, but nondiabetic patients presenting with hypoglycemia require a careful diagnostic evaluation.

DIAGNOSIS

All patients considered to have hypoglycemia should meet the criteria for "Whipple's triad": symptoms consistent with hypoglycemia, a low glucose level at the time of the symptoms, and prompt resolution of the symptoms with correction of hypoglycemia. The differential diagnosis of hypoglycemia can be broadly divided into those causes most commonly seen in otherwise healthy patients versus those seen in patients with underlying illness (Table 58.6). Essentially any critical illness can cause hypoglycemia, though this should remain a diagnosis of exclusion after consideration of any other potential causes.

A large number of medications have been reported to cause hypoglycemia (Table 58.7). Other than insulin and insulin secretagogues, most of these agents cause hypoglycemia only in rare instances.

Ethanol inhibits gluconeogenesis¹⁶⁷ by depleting hepatic nicotinamide adenine dinucleotide (NAD), impairs the counterregulatory actions of cortisol and growth hormone, and delays the response to glucagon and epinephrine. At particular risk of alcohol-induced hypoglycemia are alcoholic patients who are simultaneously malnourished and therefore glycogen-depleted as well.

In general adults with deficiencies of cortisol, with or without growth hormone deficiency, are not at increased

Table 58.7 Examples of Medications Implicated as Causative Agents for Hypoglycemia

Suspected Mechanism	Agent(s)
Accidental or malicious administration of antidiabetic agents	Insulins, sulfonylureas, glinides
Increased insulin or decreased clearance	Quinine, pentamidine, isoniazid, lithium, haloperidol, chloroquine, indomethacin ²¹⁴
Decreased hepatic glucose output	Alcohol, unripe akee fruit
Autoimmune	Isoniazid, interferon- α , hydralazine, procainamide, sulfhydryl-containing drugs
Interactions with sulfonylureas	Phenylbutazone, colchicine, paracetamol
Beta cell toxicity	Pentaminide
Unknown mechanism	Sulfonamide, salicylates, warfarin, octreotide

risk of hypoglycemia unless another condition such as pregnancy or alcohol intoxication is present. Patients with primary adrenal insufficiency who are on appropriate steroid replacement do not have an increased risk of hypoglycemia. The management of hypoglycemia related to adrenal crisis should include carbohydrates and stress dose steroids.

Given the liver's crucial role in glucose homeostasis, it is not surprising that patients with hepatic insufficiency, particularly acute liver disease, are susceptible to hypoglycemia. The kidneys are responsible for limited gluconeogenesis under normal conditions, though alterations in fasting glucose levels are not recognized until end-stage renal disease.¹⁸³ Most renal patients with significant hypoglycemia are cachectic, and therefore lack the fat or muscle stores for gluconeogenesis.

In sepsis, an increased risk of hypoglycemia results from increased glucose utilization followed by decreased glucose production¹⁸⁴ and decreased responsiveness to changes in insulin and glucagon.^{159,185} Cachexia is a rare cause of hypoglycemia,^{159,186} but has been reported in patients with severe muscle wasting or fat depletion who are therefore unable to generate glucose via gluconeogenesis. Malnourished patients are more likely to develop hypoglycemia in the setting of another disorder with increased risk of low blood sugar, such as renal insufficiency or alcohol abuse.

Insulinomas are rare (less than 1 in 250,000 patient-years) β -cell tumors that produce insulin. The tumors do not have an age or ethnic predominance, but do occur slightly more frequently in women.¹⁸⁷ Patients present with recurrent hypoglycemia associated with neuroglycopenic symptoms. Increasingly, hypoglycemia has been reported in patients following gastric bypass with a roux-en-Y procedure. Typically, the episodes occur postprandially. The precise mechanism of this phenomenon is an area of active investigation.

Suggested protocol for a prolonged diagnostic fast

- Date the onset of the fast as the time of the last food intake.
- Discontinue all nonessential medications.
- Allow the patient to drink calorie-free beverages. Ensure that the patient is active during waking hours.
- Collect samples for plasma glucose, insulin, C-peptide, proinsulin, and beta-hydroxybutyrate every 6 h until the plasma glucose concentration is less than 60 mg/dL; at that point the frequency of sampling should be increased to every 1 to 2 h.
- Samples for plasma insulin, C-peptide, and proinsulin should be sent for analysis only in those samples in which the plasma glucose concentration is less than 60 mg/dL.
- End the fast when the plasma glucose concentration is less than 45 mg/dL and the patient has symptoms and/or signs of hypoglycemia (or if 72 h have elapsed without symptoms).
- The decision to end the fast before 72 h should not be based on a low plasma glucose concentration alone, in the absence of symptoms or signs, because some healthy individuals, especially women and children, have low glucose levels during prolonged fasting.
- Alternatively, the fast can be ended when the plasma glucose concentration is less than 55 mg/dL without symptoms or signs if Whipple's triad was documented unequivocally on a prior occasion.
- A low plasma glucose concentration is a necessary, albeit not in itself sufficient, finding for the diagnosis of hypoglycemia. Therefore, the decision to end the fast should be based on laboratory-measured plasma glucose concentrations, not those estimated with a point-of care.

Figure 58.6 Suggested protocol for a prolonged diagnostic fast. (From Cryer PE, Axelrod L, Grossman AB, et al: Evaluation and management of adult hypoglycemic disorders: An Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab* 2009;94(3):709-728.)

APPROACH TO THE NONDIABETIC PATIENT WITH HYPOGLYCEMIA

Patients in the ICU often have multiple reasons to become hypoglycemic. A standardized approach to the evaluation of hypoglycemia reduces the risk of unnecessary testing. A thorough history, physical examination, and review of laboratory results often give clues to the cause of the hypoglycemia.¹⁸⁸ When a cause is evident, appropriate steps should be taken both to correct the offending problem and to increase nutritional support while the problem is being addressed. Once the acute hypoglycemic episode is treated, the appropriate steps should be taken to avoid recurrent hypoglycemia.

In a patient who satisfies Whipple's triad but lacks an obvious cause for hypoglycemia, levels of glucose, cortisol, insulin, C-peptide, proinsulin, and β -hydroxybutyrate, as well as a urine screen for sulfonylurea, should be measured during an episode of spontaneous hypoglycemia.¹⁸⁸⁻¹⁹⁰ Some patients may need to have hypoglycemia provoked by a prolonged (up to 72 hours) fast.^{188,190,191} A protocol for a prolonged fast^{188,192} is listed in Figure 58.6,¹⁸⁸ though this is not recommended in critically ill patients and should be deferred until the patient is stable. Response of glucose to IV injection of 1.0 mg glucagon may be useful in certain cases, and measurement of insulin antibodies is useful in cases in which antibody-induced hypoglycemia is suspected. An interpretation of laboratory values in hypoglycemia is presented in Table 58.8.¹⁸⁸

In a patient with documented endogenous hyperinsulinemic hypoglycemia with negative testing for oral

Table 58.8 Patterns of Clinical and Serum Chemistry Findings after Fasting or a Mixed Meal

Symptoms/ Signs	Glucose (mg/dL)	Insulin (μ U/mL)	C-peptide (nmol/L)	Proinsulin (pmol/L)	β -Hydroxy- butyrate (mmol/L)	Glucose Increase after Glucagon (mg/dL)	Circulating Oral Hypoglycemic Agent	Antibody to Insulin	Diagnostic Interpretation

IGF, insulin-like growth factor.

hypoglycemic agents and insulin antibodies, an insulinoma is sought by imaging with computed tomography, magnetic resonance imaging, or transabdominal ultrasound. Invasive imaging with endoscopic ultrasound also be performed in cases in which noninvasive imaging is unrevealing.

KEY POINTS

- Despite advances in the management of critical illness, DKA and HHS remain life-threatening emergencies.
- DKA and HHS are often precipitated by interruption of insulin treatment or an illness such as infection, but may also be the initial presentation of diabetes.
- Use of IV insulin allows for the frequent dose adjustment necessary for the successful management of hyperglycemic emergencies.
- Attention to potassium replacement is a cornerstone of the management of hyperglycemic emergencies.
- The ultimate goal of DKA management is to correct the acidosis, and the ultimate goal of HHS management is to correct the hyperosmolarity.
- Goal glucose levels for the critically ill patient are 140 to 180 mg/dL, with attention also given to avoidance of hypoglycemia.
- An HbA_{1c} on admission distinguishes between stress hyperglycemia and previously unrecognized DM, and helps guide therapy at the time of discharge.
- A physiologic insulin regimen, not oral hypoglycemic agents, is the appropriate strategy for glucose control in the hospitalized patient.
- Supplemental insulin doses ("sliding scale") can be given for unanticipated hyperglycemia, but should never be the sole therapy for hospitalized patients with diabetes.

KEY POINTS (Continued)

- Recurrent hypoglycemia blunts the normal counterregulatory response in patients with type 1 DM and predisposes to severe hypoglycemia.

SUMMARY

Adrenal diseases are infrequent primary admitting diagnoses to the intensive care unit (ICU). However, patients with unrecognized or previously diagnosed disease of the hypothalamic-pituitary-adrenal (HPA) axis may demonstrate severe decompensation in the setting of other critical illness.

Adrenal insufficiency (AI) is by far the most common adrenal disorder seen in the ICU and is the focus of this chapter. It occurs more frequently in critically ill patients than in general hospitalized patients and represents a true emergency that requires rapid diagnosis and treatment. If missed, the condition can be fatal. In addition, because critical illness is often the precipitant of overt AI, the intensivist may have the first and only chance to make the diagnosis.¹

Primary AI results from a subtotal or complete destruction of the adrenal cortex (>90%) and results in cortisol, aldosterone, and androgen deficiency. Multiple causes of primary AI include autoimmune destruction (Addison's disease), polyendocrine deficiency syndrome, infections (e.g., tuberculosis, fungus), vascular compromise, primary or metastatic cancer, amyloidosis, and surgical removal of the adrenal glands.

Secondary AI is much more common than primary AI and can be traced to a lack of adrenocorticotrophic hormone (ACTH). Without ACTH to stimulate the adrenal glands, production of cortisol falls but aldosterone secretion

remains intact. The most common cause of secondary AI is the inadvertent abrupt withdrawal of therapeutic exogenous corticosteroids. Another cause of secondary AI is the surgical removal of benign or noncancerous, ACTH-producing tumors of the pituitary gland (Cushing syndrome). In this case the source of ACTH is suddenly removed, and replacement hormones must be taken until normal ACTH and cortisol production resumes.

Less commonly, secondary AI occurs when the pituitary gland reduces or ceases production of ACTH. This can occur for a variety of reasons including tumors or infections of the area, loss of blood flow to the pituitary, radiation for the treatment of pituitary tumors, total or subtotal removal of the hypothalamus, and surgical removal of the pituitary gland.

The term relative adrenal insufficiency has been replaced in recent literature by critical illness–related corticosteroid insufficiency (CIRCI),^{2,3} which in simple terms is inadequate corticosteroid activity for the severity of the illness of a patient. Similar to type II diabetes (relative insulin deficiency), CIRCI is thought to arise because of corticosteroid tissue resistance and inadequate circulating levels of free cortisol.

Patients at risk of AI vary from young athletes on steroids to persons taking adrenal extracts for “adrenal fatigue syndrome.” Also at risk are those receiving chronic topical glucocorticoids for dermatologic disorders. Patients who are

on glucocorticoids and inhibitors (such as itraconazole, diltiazem) of CYP3A4 are at risk as well.⁴ For all these reasons the intensivist must understand clinical problems associated with the HPA axis and the use of glucocorticoid hormones.

INCIDENCE AND PREVALENCE

The actual incidence of acute AI is unknown. The incidence of HPA axis failure varies depending on the criteria used to make the diagnosis and the patient population studied. The overall incidence of AI in critically ill patients is estimated to be as high as 60% in patients with severe sepsis and septic shock.⁵ At least 90% of both adrenal glands must be destroyed before clinical and biochemical manifestations of AI occur. Tissue hypoxia, a relatively common disorder in critically ill patients, has little effect on the synthesis of cortisol. Secondary AI may be more common than primary AI. The clinical presentation of secondary AI is relatively nonspecific and often resembles other conditions common in the ICU. Hence it is not uncommon to attribute the clinical features resulting from acute AI to commonly seen medical conditions in the ICU.⁶

PATHOPHYSIOLOGY

To understand the pathogenesis of adrenal diseases one must understand the physiology of the adrenal glands and the causes that result in the disruption of the physiologic process.

The adrenal glands are pyramid-shaped, each weighing about 5 to 10 g, and located just superior to their respective kidneys. The left adrenal gland is usually slightly more cephalad than the right. Each adrenal gland is composed of an inner medulla and outer cortex. These layers are embryologically, anatomically, and physiologically distinct. The adrenal cortex is responsible for the secretion of multiple steroid hormones. The adrenal medulla is responsible for the secretion of catecholamines.

The adrenal cortex is composed of three zones: the outer zona glomerulosa, inner zona fasciculata, and zona reticularis. The zona glomerulosa secretes the mineralocorticoid aldosterone in response to angiotensin, ACTH, and a high circulating potassium concentration. The zona fasciculata and zona reticularis secrete glucocorticoids and adrenal androgens.

The principal mineralocorticoid is aldosterone, which is regulated not only by ACTH but also by serum sodium and potassium levels and by the renin-angiotensin system.^{7,8} Mineralocorticoids exert their primary effect on distal renal tubule cells, resulting in renal sodium retention at the expense of potassium loss in the urine. A third major class of adrenal steroids is the sex hormones: dehydroepiandrosterone (DHEA), DHEA-sulfate, and androstenedione. Like the glucocorticoids, ACTH primarily regulates these steroid hormones. They function mainly as precursors for the primary circulating androgen, testosterone, and also may undergo separate conversion to estrogen hormones. In critically ill patients, glucocorticoids are the steroid hormones of greatest concern and therefore remain the focus of the remainder of this discussion.

GLUCOCORTICOID SYNTHESIS

Glucocorticoid synthesis is regulated by (1) a negative feedback mechanism involving cortisol and adrenal steroids, (2) a diurnal rhythm, and (3) stress. The hypothalamus and the pituitary gland closely regulate adrenal hormone production. Corticotropin-releasing hormone (CRH) is produced in the hypothalamus and acts on specialized cells in the pituitary, stimulating production of ACTH, which serves, in turn, to stimulate adrenal cortical cells to produce numerous steroid hormones, including cortisol. Adrenal hormones have a negative influence at the level of the hypothalamus and the pituitary, inhibiting CRH and ACTH release. The adrenal gland in turn ceases its secretory activity until the cortisol concentration returns to normal. When serum cortisol levels are below normal, secretion of CRH and ACTH increases, stimulating the adrenal glands to produce cortisol until its level normalizes. Therefore, abnormalities in circulating serum levels of adrenal steroid hormone can be caused by either adrenal or hypothalamic pituitary disease. Because ACTH possesses α -melanocyte-stimulating hormone activity, excessive production of ACTH is associated with hyperpigmentation.

Cortisol is normally secreted in a diurnal pattern. The circulating cortisol level is increased in the morning hours, at approximately 8 AM. Serum cortisol concentrations decrease throughout the remainder of the day.⁹ Similarly, the serum cortisol response to ACTH stimulation also varies in a circadian rhythm. Afternoon responsiveness is much greater because of the decreased circadian level of cortisol at that time. In addition, cortisol is secreted in a series of pulses rather than in a continuous fashion. These factors contribute to make interpretation of a random cortisol level and the ACTH-stimulated value difficult.

"Stress" (exemplified by sepsis, major surgery, or trauma) also affects glucocorticoid synthesis.¹⁰⁻¹² The *stress response* is characterized by continuous ACTH secretion despite a high serum cortisol concentration. Stress overrides all other regulatory mechanisms of cortisol secretion by the adrenal cortex and increases cortisol secretion irrespective of the time of day or the current serum cortisol concentration. The mechanism by which the HPA axis is regulated during stress is not clearly understood. Periventricular neurons in the hypothalamus respond to stress by increasing the levels of CRH messenger ribonucleic acid (mRNA).^{13,14} It has been shown that production of the cytokines interleukin 1 (IL-1), interleukin 6 (IL-6), and tumor necrosis factor- α (TNF- α) also plays an important role in the regulation of the HPA axis.¹⁵⁻¹⁹ The cortisol secretion that occurs because of the activation of the HPA axis causes an inhibitory effect not only on the secretion of CRH and ACTH but also on the liberation of interleukins.²⁰ Thus, there is a functional loop between immune activation and regulation of the HPA axis during stress.

The stress response is biphasic, consisting of an early phase in which both ACTH and cortisol are elevated and a late phase in which the serum cortisol level is elevated but the serum ACTH level is paradoxically low.⁸ This is explained by the fact that endothelin and atrial natriuretic peptide are both elevated in severe illnesses. Endothelin increases cortisol production by the adrenals, whereas the atrial natriuretic peptide inhibits ACTH production by acting at the

hypothalamic-pituitary level. Vasopressin and angiotensin II can increase ACTH secretion during stress conditions, such as sepsis and septic shock.

Acute respiratory failure causes a 50% to 100% rise in serum cortisol concentration. A twofold to sixfold rise occurs with septic shock and following surgical procedures and trauma. The rise in serum cortisol correlates positively with severity of illness⁶ and negatively with survival.⁷

The normal daily output of cortisol by the adrenal glands is 20 to 30 mg. The normal adrenal gland secretes about 10 to 12 times the normal daily output of cortisol when under maximal physiologic stress. Hence approximately 200 to 300 mg of hydrocortisone or its equivalent is considered a daily “stress dose” of glucocorticoid.

GLUCOCORTICOID ACTIONS

After uptake of free hormone from the circulation, the effects of cortisol and aldosterone are mediated by binding to intracellular receptors termed the glucocorticoid receptor and the mineralocorticoid receptor.

CARDIOVASCULAR EFFECTS

Glucocorticoids help to maintain vascular tone and cardiac contractility. The presence of glucocorticoids is important to the physiologic effects of catecholamines on vascular smooth muscle. Glucocorticoids affect blood pressure by different mechanisms including direct action of glucocorticoids on the vasopressor action of catecholamines, and glucocorticoid-induced decrease in the levels of prostaglandin E₂ and kallikrein (vasodilators). Angiotensinogen synthesis is increased by glucocorticoids.²¹ Glucocorticoids increase the synthesis of β -adrenergic receptors, reverse β_2 -adrenergic receptor dysfunction, and increase the coupling of the receptor with the second messenger system.²²

Two hemodynamic states have been described during acute AI:

1. Low cardiac output, high systemic vascular resistance shock is caused by both decreased myocardial contractility and decreased preload.
2. High cardiac output, low systemic vascular resistance shock mimics septic shock.²³ It appears that patients with AI present initially with a combination of cardiogenic shock and hypovolemic shock. Intravascular volume expansion with intravenous fluids results in an increase in cardiac output and a lowering of systemic vascular resistance. The hemodynamic profile that one sees depends on the timing of pulmonary artery catheter placement during the course of treatment in an individual patient. Thus, the hypotension of AI can mimic cardiogenic, hypovolemic, or septic shock (depending on when the hemodynamic assessment was made) and may be poorly responsive or unresponsive to treatment with fluids and vasopressors in the absence of glucocorticoid therapy.

METABOLIC EFFECTS

Glucocorticoid hormones have profound influence on carbohydrate metabolism. A major action is on gluconeogenesis. Glucocorticoids increase hepatic glycogen and glucose

by inducing the synthesis of hepatic enzymes and increasing the availability of gluconeogenic substrates. This is because of glucocorticoid-induced proteolytic activity on peripheral tissues, which causes mobilization of glycogenic amino acid precursors from peripheral supporting structures such as bone, skin, muscle, and connective tissue because of protein breakdown and inhibition of protein synthesis. Glucocorticoids decrease the peripheral uptake and utilization of glucose. They have a permissive effect on other hormones such as glucagon and catecholamines, thus serving to increase the circulating glucose concentration, which in turn increases insulin secretion.

Glucocorticoids also affect fat and protein metabolism. They increase lipolysis both directly and indirectly by action on other hormones. Glucocorticoids regulate fatty acid mobilization by enhancing activation of cellular lipase by lipid-mobilizing hormones (e.g., catecholamines, pituitary peptides). They elevate free fatty acid levels in the plasma and enhance any tendency to ketosis. Glucocorticoids stimulate peripheral protein metabolism, using the amino acid products as gluconeogenic precursors. Glucocorticoids inhibit RNA synthesis in most body tissues, but in the liver they stimulate RNA synthesis.

RENAL EFFECTS

Glucocorticoids bind to the mineralocorticoid receptors in renal tubules and increase sodium reabsorption and excretion of potassium and hydrogen ions. Glucocorticoids increase the glomerular filtration rate, proximal tubular epithelial sodium transport, and free water clearance.²¹ Glucocorticoids also increase free water excretion by inhibiting the release of antidiuretic hormone (ADH).

IMMUNOLOGIC EFFECTS

Glucocorticoids suppress immunologic responses, and this is the basis for their use in the treatment of autoimmune and inflammatory disorders. In the peripheral blood, they redistribute lymphocytes from the intravascular compartment to the lymphoid pool in the spleen, lymph nodes, and bone marrow. They therefore decrease lymphocyte counts, but neutrophil counts increase after glucocorticoid administration. Eosinophil counts fall, due to eosinophil apoptosis. The immunologic actions of glucocorticoids are mediated through T and B lymphocytes. Glucocorticoids inhibit immunoglobulin synthesis and cytokine production from lymphocytes. Glucocorticoids also inhibit monocyte differentiation into macrophages and plasminogen activators.²¹

Glucocorticoids mediate anti-inflammatory effects by stabilizing lysosomal membranes. They also decrease the release of inflammatory mediators such as histamine, cytokines, and prostaglandins.

The immunologic actions of glucocorticoids are only significant in circumstances in which they are present in supraphysiologic amounts such as markedly increased endogenous production or exogenous administration.

GASTROINTESTINAL EFFECTS

It has been postulated that CRH inhibits the release of motilin, a duodenal hormone that is responsible for the initiation of peristaltic contractions, which begin in the stomach and propagate distally. Glucocorticoids decrease

CRH production and thus inhibit gastric and intestinal motility. This could explain the vomiting, constipation, and abdominal pain seen in cortisol deficiency. Glucocorticoids can also increase risk of peptic ulcer disease and pancreatitis.

CALCIUM METABOLISM

Glucocorticoids lower serum calcium levels by several mechanisms. They inhibit calcium absorption from the gut, decrease renal calcium reabsorption (which results in hypercalciuria), and promote shift of calcium from the extracellular compartment to the intracellular compartment. Glucocorticoids inhibit osteoblast function and cause osteoporosis, which occurs in approximately 50% of patients who require long-term glucocorticoids.²⁴ Avascular necrosis is a dreaded complication.²¹ It mainly affects the femoral head and causes pain and collapse of the bone, often necessitating hip replacement. This effect is not necessarily dose dependent.

OTHER EFFECTS

Glucocorticoids have many other effects, including the ability to produce significant mood changes and even psychosis in some patients. Glucocorticoids have an association with cataract formation and increased intraocular pressure both by increasing aqueous humor production and decreasing drainage. They also affect the production and action of a number of other hormones including insulin, thyroid hormones, and gonadal hormones.

Aldosterone secretion is regulated mainly by the renin-angiotensin system. The most potent modulator of this system is renal perfusion. Hyperkalemia inhibits production of renin but increases the synthesis of aldosterone. Aldosterone increases sodium reabsorption in the collecting tubules and at the same time causes potassium and hydrogen ion excretion. This is mediated by the Na^+/K^+ pump in the presence of the enzyme Na^+/K^+ -ATPase and results in sodium and water retention and an increase in intravascular volume.²¹

Hyperkalemia, hyponatremia, non-anion gap metabolic acidosis, hemoconcentration, and hypovolemia provide important clinical clues to the diagnosis of primary AI. Because ACTH is not a potent regulator of aldosterone secretion, secondary AI is usually not associated with hyperkalemia. Hyponatremia and hypovolemia may be present in secondary AI but not to the degree found in primary AI. The renin-angiotensin system is activated during AI and serves as a defense mechanism to improve the low intravascular volume and the altered vasomotor tone that results from aldosterone and cortisol deficiency.^{25,26}

ETIOLOGY AND PATHOGENESIS

Causes of primary AI have been previously discussed and are shown in [Box 59.1](#).

AUTOIMMUNE DISEASE

Autoimmune disease (Addison's disease) is currently the most common cause of primary AI and accounts for approximately 80% of cases. For many years tuberculosis was the

most common cause. AI may occur as isolated disease or as part of a polyglandular autoimmune syndrome associated with thyroiditis, diabetes mellitus (Schmidt's syndrome), hypogonadism, vitiligo, and pernicious anemia.²⁷⁻²⁹ Autoimmune AI is more common in women than men and usually occurs in the third to fifth decades of life. The mean duration of symptoms before diagnosis is approximately 3 years. In this disorder high levels of circulating autoantibodies attack the cytoplasm of adrenal cortical cells and inhibit synthesis of glucocorticoids.^{27,28}

INFECTIOUS DISEASE

TUBERCULOSIS

The second most common cause of primary AI is adrenal gland destruction by *Mycobacterium tuberculosis*. This infection currently accounts for less than 20% of cases.³⁰ This usually occurs in the presence of tuberculosis elsewhere in

the body, especially with involvement of the lungs, genitourinary system, and gastrointestinal system. AI is usually manifest years after the initial presentation of tuberculosis.³¹ The mean duration of symptoms of AI prior to diagnosis is 6 to 9 months. AI secondary to tuberculosis occurs with equal frequency in men and women. In contrast to autoimmune adrenalitis, tuberculosis-induced adrenal disease is not associated with other endocrine diseases. In addition, with tuberculosis the adrenal glands are enlarged and may be calcified. In contrast, the adrenal glands in autoimmune adrenalitis are usually atrophied and noncalcified.

FUNGAL DISEASE

Fungal disease can also cause primary AI. *Histoplasma capsulatum* is the most common organism. As seen in tuberculosis, fungal infection is usually disseminated and involves organs other than the adrenal glands. Adrenal involvement may be seen during the active phase or may develop years later after the disease has become “inactive.” Sarosi and colleagues³² reported that more than 50% of patients with disseminated histoplasmosis had AI, and AI was the most common cause of death.

ACQUIRED IMMUNODEFICIENCY SYNDROME

Patients with acquired immunodeficiency syndrome (AIDS) are at risk of developing AI by several different mechanisms. Fungal infections are more common in this patient population, and disseminated disease may involve the adrenal glands. Similarly, mycobacterial infection, cytomegalovirus infection, and Kaposi sarcoma may cause involvement of the adrenals in up to 50% of patients.³ In addition, sepsis and spontaneous adrenal hemorrhage are also seen in this group of patients. Because patients with human immunodeficiency virus (HIV) infection now survive longer, an increased incidence of AI is likely.

NEOPLASIA

Neoplastic metastasis to the adrenal glands has been found on autopsy in 27% to 40% of patients who die of malignancy.³³⁻³⁶ Yet metastatic carcinoma accounts for less than 1% of cases of primary AI.³³ This finding is explained by the tremendous functional reserve possessed by the adrenal glands. More than 90% of the adrenal gland must be destroyed before hypofunction occurs. Many patients with metastasis to the adrenals do not develop hormonal deficiency.³⁷ The most common neoplasms to involve the adrenals are lung cancer, breast cancer, melanoma, and lymphoma.³⁵ AI usually occurs in the setting of widespread metastatic disease and is rarely the initial manifestation of malignancy.

MEDICATIONS

Certain medications can cause AI. Of particular interest to the intensivist are ketoconazole, phenytoin, phenobarbital, rifampin, and etomidate. Ketoconazole decreases glucocorticoid production and is also a glucocorticoid receptor antagonist. Etomidate decreases glucocorticoid production. Phenytoin, rifampin, and barbiturates increase the catabolism of glucocorticoids. These medications can precipitate

acute AI by decreasing glucocorticoid production or function in a patient who has compromised adrenal reserve.

ADRENAL HEMORRHAGE

Adrenal hemorrhage is an important but uncommon cause of AI in the ICU. The association of adrenal hemorrhage with fulminant sepsis was first described with *Neisseria meningitidis* (Waterhouse-Friderichsen syndrome). Infections with *Streptococcus pneumoniae*, *Pseudomonas* species, and *Haemophilus influenzae* type b can also cause this syndrome.

Besides the infectious causes, other conditions may predispose to adrenal hemorrhage, including severe illness (particularly cardiac disease), coagulopathy, anticoagulant therapy, thromboembolism, burns, and trauma.³⁸ Under these circumstances the typical signs and symptoms of AI are often mistaken for those of other common conditions. Typical settings include the patient who is in the first or second postoperative week or a patient who has been started recently on anticoagulation therapy. Common findings include abdominal, back, flank, or chest pain; nausea; vomiting; fever; altered mental status; orthostatic hypotension; and a sudden drop in hematocrit. The hemodynamic crisis associated with adrenal hemorrhage occurs 1 to 3 days after the initial hemorrhage.

ETIOLOGY OF SECONDARY ADRENAL INSUFFICIENCY

Causes of secondary AI have been discussed previously and are shown in [Box 59.2](#). Secondary AI occurs because of a decrease in ACTH caused by either hypothalamic-pituitary disease or suppression of the HPA axis as a result of glucocorticoid therapy. The most common cause today is discontinuation of corticosteroid therapy. Chronic glucocorticoid therapy leads to HPA axis suppression with resulting secondary AI if glucocorticoids are abruptly discontinued. With the exception of AI because of discontinuation of chronic glucocorticoid therapy, secondary adrenocortical insufficiency is much less common than primary AI. Isolated ACTH deficiency is rare, and ACTH is the last pituitary hormone to be impaired by enlarging sellar and suprasellar tumors.

Most patients admitted to the ICU with secondary AI have recently received steroid therapy or have taken steroids within the year prior to admission. No clear evidence indicates that detailing the duration or dose of steroid therapy predisposes patients to adrenal suppression. Doses of 25 mg of prednisone twice a day for 2 days, 12.5 mg per day for 6 months, or 5 mg per day for 5 years have all been shown to cause adrenal suppression. On the other hand, studies have shown that prednisone in doses less than 40 mg per day given every morning for 5 to 7 days did not cause adrenal suppression.³⁹

As a practical guideline, all patients who have taken 40 mg of prednisone per day or its equivalent for a period greater than 2 or 3 weeks should be considered to be adrenal insufficient until proved otherwise. If glucocorticoids have been given to a patient for more than 1 to 2 weeks, they should be tapered off to allow time for the adrenal glands to recover function. AI can occur in response to stress as long as 1 year after steroids are discontinued.⁴⁰ All of these patients should be evaluated for adrenal function and

CLINICAL FEATURES

Common symptoms and signs of AI are shown in [Box 59.3](#). The symptoms, signs, and general laboratory data seen in AI are nonspecific. However, when taken together they form a pattern of findings that should suggest the possibility of AI. Patients with acute AI share many characteristics with patients who have chronic AI, but the symptoms are usually more severe in the acute setting. Virtually all patients complain of weakness, fatigue, and loss of appetite. They also complain of nausea and diarrhea with occasional vomiting and abdominal pain. Infrequently, patients note myalgias, arthralgias, and dizziness caused by orthostatic hypotension. Weight loss can occur. The classic presentation of acute AI is a patient with unexplained hemodynamic instability who is unresponsive to intravascular volume resuscitation and use of vasopressors. Patients with primary AI may have hyperpigmentation of the tongue, buccal mucosa, palmar creases, and scar tissue. This is caused by increased production of ACTH from the pituitary. Hyperpigmentation is notably absent in secondary AI. If the underlying problem is autoimmune adrenalitis, the patient may have

vitiligo, pernicious anemia, or one of the other associated endocrinopathies.

DIAGNOSIS

The diagnosis of AI demands a high index of suspicion. The classic symptoms, signs, and laboratory findings of AI are not commonly seen. The consequences of missing the diagnosis can be lethal, but if the diagnosis is made the condition can usually be treated easily. If the diagnosis of AI is being considered, the patient's history should be carefully reviewed for use of steroids (especially in the past year), exposure to tuberculosis, use of anticoagulant therapy, presence of sepsis, or history of cancer that may have metastasized to the adrenals. Patients on high doses of steroids can develop AI when subjected to stress.

LABORATORY FINDINGS

Laboratory evaluation of patients with suspected AI is essential. In a patient with acute worsening of a chronic hypoadrenal state, the common laboratory findings shown in [Box 59.4](#) are more likely to be present and are likely to be more pronounced. Electrolyte abnormalities depend on the type of deficiency: a combined glucocorticoid and

mineralocorticoid deficiency (typically seen in primary AI) or an isolated glucocorticoid deficiency (characteristic of secondary AI).

Patients who have a combined deficiency may show hyponatremia, hyperkalemia, decreased serum bicarbonate, and increased blood urea nitrogen (BUN). This is primarily caused by the mineralocorticoid deficiency, which leads to renal sodium loss, potassium retention, and dehydration with acidosis and prerenal azotemia. Patients with secondary adrenocortical deficiency usually have milder electrolyte abnormalities. Their normal adrenal glands are able to produce sufficient amounts of mineralocorticoid even in the absence of ACTH stimulation. They usually have mild hyponatremia with normal potassium levels, and they show little evidence of dehydration. Patients with AI may also have hypoglycemia. This occurs as a result of increased utilization of glucose and decreased gluconeogenesis in the face of glucocorticoid deficiency.

DIAGNOSTIC TESTS

When there is a high suspicion of AI, hormonal testing is necessary to confirm the diagnosis. The laboratory evaluations most commonly used to detect AI in critically ill patients are the random serum cortisol level and the rapid ACTH stimulation test.

SERUM CORTISOL LEVEL

The biochemical diagnosis of AI is controversial. It is based on the demonstration of decreased cortisol production. Most clinical laboratories routinely measure total rather than free cortisol levels. Experts have recently suggested that measurement of free cortisol levels makes more physiologic sense, but studies have not helped establish diagnostic thresholds for free cortisol levels.⁴¹ In addition, variability of cortisol assays can confound the diagnosis of AI.⁴²

Given the controversy in diagnosis, the following recommendations are made. A randomly measured serum cortisol level that exceeds 44 µg/dL makes the diagnosis of adrenocortical deficiency unlikely.⁵ Serum cortisol levels increase significantly in patients with normal adrenal function who are in shock and critically ill. The finding of a random serum cortisol level of less than 10 µg/dL in this setting is highly suggestive of compromised adrenal function and should prompt treatment or a confirmatory ACTH stimulation test.⁵

One must be careful in the interpretation of random serum cortisol levels in patients treated with several commonly used drugs in the ICU. Propofol produces a temporary reduction in serum cortisol levels. However, it does not seem to inhibit adrenal responsiveness to ACTH. Etomidate, on the other hand, is associated with a reduced serum cortisol concentration despite ACTH stimulation.⁴³

RAPID ACTH STIMULATION TEST

The ACTH stimulation test measures the response of the adrenal gland to stimulation by exogenous ACTH. This test can be performed at any time of the day because the normal diurnal variation of cortisol is lost in the setting of critical illness. A blood sample is drawn, and a baseline serum cortisol level is measured. Cosyntropin (synthetic ACTH) 250 µg is then administered intravenously. Repeat samples

are drawn at 60 minutes. Although controversial, some studies have shown that a low dose of ACTH (1 to 5 µg) produces a similar response as the 250 µg dose, especially in patients with AI that is recent or new onset.^{44,45}

An increase in serum cortisol of less than 9 µg/dL following 250 µg of cosyntropin is highly suggestive of AI regardless of the baseline cortisol level. An increase in serum cortisol of greater than 17 µg/dL or total cortisol level of 44 µg/dL or greater suggests adrenal competence. When the baseline cortisol level is between 10 and 44 µg/dL, and the cortisol increment after cosyntropin stimulation is between 9 and 17 µg/dL, metyrapone testing is needed to assess adrenal function.⁵

The rapid ACTH stimulation test is a relatively simple test for evaluating AI.⁴⁶ It does not, however, differentiate between primary and secondary AI. To differentiate between primary and secondary AI, a basal plasma ACTH determination is made. A serum cortisol measurement is then made following a continuous 48-hour infusion of ACTH. An increased basal ACTH (>250 pg/mL) or a serum cortisol level (<20 µg/dL) after 48 hours of ACTH stimulation is compatible with primary AI. On the other hand, a decreased basal ACTH and a high cortisol level after ACTH administration suggest secondary AI.

CRITICAL ILLNESS-RELATED CORTICOSTEROID INSUFFICIENCY

The term critical illness-related corticosteroid insufficiency (CIRCI) describes HPA axis dysfunction in critical illness, which is defined as a cellular corticosteroid activity that is inadequate for the severity of the patient's illness. The use of the term relative adrenal insufficiency is no longer recommended by some authors.

Despite no conclusive evidence of benefit, in the 1950s, 1960s, and into the 1970s cortisol at low doses over days was often used in patients with severe manifestations of sepsis to counter the AI that was assumed to be present. This was based on autopsy studies that revealed adrenal necrosis in patients dying with severe infection. The subsequent recognition of the systemic effects of inflammation in sepsis and the discovery that the majority of patients in septic shock had normal or increased cortisol levels led to a paradigm shift in treating septic shock with massive doses of steroids given for a short period of time. This practice was based on animal studies showing that large doses of steroids given prior to boluses of endotoxin or gram-negative bacteria prevented death.⁴² Clinical trials testing the utility of several large doses of steroids in patients with septic shock failed to show benefit.^{47,48}

One study in patients with septic shock demonstrated that regardless of baseline cortisol level, the inability to raise the cortisol level following ACTH stimulation by at least 10 µg/dL signified poor prognosis.⁴⁹ Of this poor prognostic group, the higher the baseline cortisol level with failure to produce a 10 µg/dL increase, the worse the prognosis.

MANAGEMENT

Once the diagnosis of AI is made, a search for the cause should be initiated as the patient is being stabilized. To rule

out tuberculosis, a purified protein derivative (PPD) skin test must be placed and a chest radiograph performed. An abnormal prothrombin time, partial thromboplastin time, or platelet count may point to an unsuspected coagulopathy suggesting the possibility of adrenal hemorrhage. Antiadrenal antibodies are found in about 70% of patients with autoimmune adrenal disease and in less than 0.1% of normal subjects.⁵⁰ Computed tomography scanning of the abdomen is useful in determining the size and presence of calcification of the adrenal glands. Adrenal calcification can be seen in 53% of cases of tuberculosis.⁵¹

Management of AI can be best accomplished by identifying the degree of acuteness and severity of the patient's illness at the time of presentation.⁵²

PREEXISTING ADRENAL INSUFFICIENCY

Patients who are known to have AI or who have received glucocorticoid therapy in the past year should receive stress doses of corticosteroids during critical illnesses and during surgical procedures. Hydrocortisone 100 mg IV bolus is administered followed by 100 mg as an intravenous infusion every 6 to 8 hours. Isotonic saline is administered intravenously in volumes sufficient to support blood pressure. Five percent dextrose in isotonic saline may be used in the hypoglycemic patient. Once the acute insult has resolved, the hydrocortisone should be tapered to a maintenance dose. The replacement dose is usually 5 mg of prednisone or 30 mg of hydrocortisone each day.

Patients with known AI scheduled for operation should continue the existing steroid dose prior to surgery. The morning of the operation hydrocortisone 100 mg is given intravenously. During the operation a 100-mg hydrocortisone infusion is given. Following surgery 100 mg of hydrocortisone is administered intravenously every 8 hours during the first postoperative day. The dose is then tapered back to the baseline steroid dose over the next 3 to 4 days.

Adequate instruction is important in this group of patients. Patients with AI should be advised to wear a medical alert bracelet. These patients should be provided with a parenteral form of glucocorticoid and taught to self-administer the drug in case of emergency. They should be taught about the clinical situations in which increased amounts of glucocorticoids are required.

HEMODYNAMICALLY STABLE PATIENT

A patient who is suspected of having AI and who is hemodynamically stable should be managed in the following manner. A serum cortisol level and a rapid ACTH stimulation test should be performed prior to initiation of stress doses of corticosteroids. Hypovolemia should be treated with isotonic saline. If the diagnosis of AI is confirmed, hydrocortisone 100 mg should be administered as an intravenous infusion every 6 to 8 hours.

HEMODYNAMICALLY UNSTABLE PATIENT

Acute AI is a life-threatening emergency and requires immediate and aggressive therapy to ensure prompt recovery. A patient who is suspected of having AI and who is hemodynamically unstable should be managed in the following

manner. Immediate glucocorticoid therapy and intravenous administration of isotonic fluids are warranted. Blood should be obtained for baseline serum cortisol concentration, electrolytes, glucose, BUN, and creatinine.

The dose of hydrocortisone is 100 mg IV bolus followed by 100 mg IV every 6 hours. After the patient has stabilized, the hydrocortisone is tapered at 10 to 15 mg per day until a maintenance dose of 30 mg per day is achieved.

Vigorous intravascular volume expansion with saline-containing solutions is recommended. Volume resuscitation is usually initiated with 0.9% normal saline. Dextrose 5% in saline is added to prevent hypoglycemia. The patient's fluid, electrolyte, and glucose status should be carefully monitored during resuscitation. In general, patients with acute AI have a deficit that is approximately 20% of their extracellular space. The rapidity of infusion depends on the patient's hemodynamic status and the presence or absence of underlying cardiovascular disease. A pulmonary artery catheter may be helpful in monitoring hemodynamic status and guiding fluid therapy. Vasopressors may be necessary in the initial stages to maintain an adequate blood pressure to ensure tissue perfusion. In general, if the hypotension is caused by AI, improvement in blood pressure should be seen within 6 hours of corticosteroid therapy.

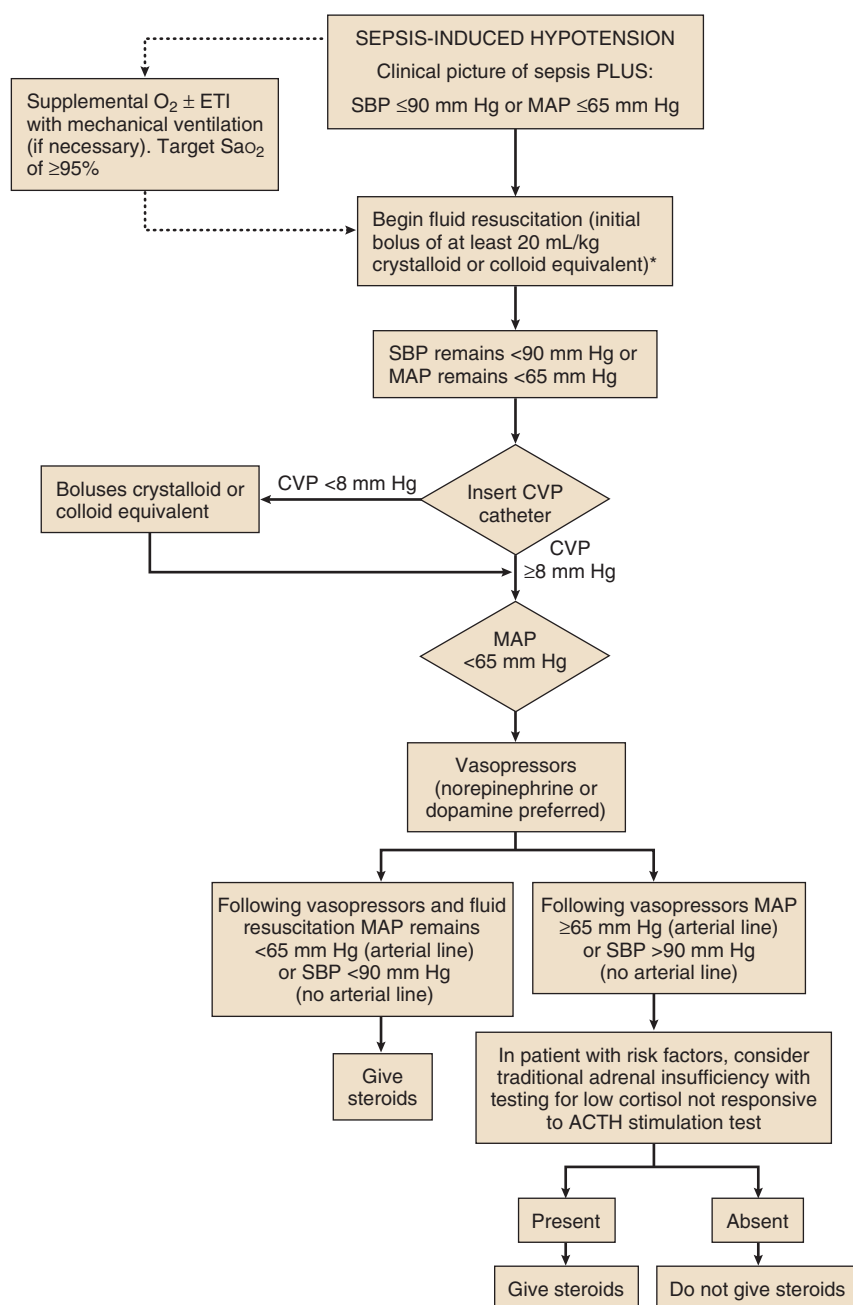

Mineralocorticoid administration is usually not required initially during acute AI, because the large doses of hydrocortisone provide adequate mineralocorticoid activity. Once the acute event has resolved and the hydrocortisone is tapered to less than 100 mg per day, mineralocorticoids should be started. Fludrocortisone is recommended at a dose of 0.05 to 0.20 mg per day. Excess mineralocorticoids can cause congestive heart failure, hypokalemia, and metabolic alkalosis.

In patients with concurrent hypothyroidism, glucocorticoid replacement should begin prior to thyroid hormone replacement. Administration of thyroid hormone increases the metabolism of glucocorticoids. Thus treatment with thyroid hormone before glucocorticoid therapy might worsen the hypoadrenal state and precipitate AI.

Reversal of the underlying cause of adrenal dysfunction is an important aspect of treatment. The precipitation of acute adrenal failure is provoked by another acute process and thus the causes of both primary and secondary AI should be sought. Prophylactic use of antibiotics is not beneficial, but specific infections should be treated aggressively with appropriate antibiotic therapy.

SEVERE SEPSIS AND SEPTIC SHOCK

Six randomized clinical trials suggest that replacement of moderate-dose hydrocortisone (200-300 mg/day) decreases the need for vasopressor support in patients with septic shock.^{2,53} Among them, the two larger trials were better powered to detect a survival difference but had differing results. These differences were attributed in part to varying demographics and other factors. In the Corticus study, hydrocortisone did not decrease mortality rate in both responders and nonresponders to ACTH, but the patients who received hydrocortisone had more rapid resolution of shock, which has been seen in other studies as well. These results were different from the Annane study, in which the nonresponders to ACTH had both reduction in mortality

* In circumstances where MAP is judged to be critically low, vasopressors may be started at any point in this algorithm.

Figure 59.1 Algorithm for management of severe sepsis/septic shock. CVP, central venous pressure; ETI, endotracheal intubation; MAP, mean arterial pressure; SBP, systolic blood pressure.

rate and reversal of shock. The differences were attributed in part to the fact that in the Annane study, the patients enrolled were sicker, patients had higher SAPS II scores, and time to enrollment differed (8 hours versus 72 hours in the Corticus study). The Corticus study was published some years after the Annane study; it is possible that variations in the supportive care of the critically ill with advances in the care of the septic patient in the last few years could have made it difficult to show a mortality rate difference in Corticus. More patients in the Corticus study had a surgical source of sepsis, and thus source control may have played a bigger role in improving outcomes. In addition,

fludrocortisone was not administered in the Corticus study. The duration of steroid therapy was different in the two studies, and this could have caused the differing results. In addition, Corticus had a higher rate of superinfection. Compounding all these issues is the difficulty surrounding the accurate diagnosis of AI.^{53,54} However, in a recent study, the addition of enteral fludrocortisone did not result in a significant improvement in hospital mortality rates.⁵⁵

In the trials mentioned here, there was resolution of shock in both responders and nonresponders to ACTH stimulation. The decision to treat patients with septic shock with hydrocortisone should, therefore, probably not be

based on the results of a random total cortisol level or the response to cosyntropin. If a clinician decides to perform an ACTH test, until the test is performed, treatment with dexamethasone in patients with septic shock should not be done because of the possibility that a single dose of a long-acting corticosteroid may cause prolonged suppression of the hypothalamic-pituitary axis.²

Once initiated, hydrocortisone should ideally be continued for about 7 days. At the present time, the optimum duration of therapy is not clear, but data from studies would suggest that abrupt discontinuation of hydrocortisone could precipitate a rebound inflammatory response and recurrent shock. The ideal dose of steroid should help decrease the proinflammatory responses and at the same time minimize adverse effects, such as interference with wound healing, and decrease any negative impact on immune function. From studies, it appears that adverse effects of myopathy and superinfections are more common with doses greater than 200 to 300 mg/day of hydrocortisone. Hydrocortisone can be administered as a bolus dose or as a continuous infusion. Continuous infusions tend to cause less glycemic fluctuations.

To date, no studies document an improved outcome with corticosteroid use in the absence of septic shock (Fig. 59.1).

ADDITIONAL INDICATIONS FOR CORTICOSTEROIDS

Observational studies suggest that stress doses of corticosteroids may have a role in the management of critically ill patients with liver failure and cardiac surgery. Additional large randomized studies are needed in these areas.³

ETOMIDATE

Etomidate is a drug increasingly used as an induction agent for endotracheal intubation. It has the advantage of not causing hemodynamic instability. This drug inhibits the 11 β -hydroxylase enzyme that converts 11-deoxycortisol into cortisol in the adrenal gland, and can cause AI. This adverse event has been described with single bolus and continuous infusions.

Additional randomized clinical trials are needed in this area to determine the clinical significance of this agent in causing AI septic shock and the effect on mortality rate, given that the incidence of AI in septic patients can be as high as 60%.⁴³

SUMMARY

Management of acute AI involves prompt diagnosis and immediate treatment to prevent cardiovascular collapse and

death. A high index of suspicion is necessary because the condition can be lethal if missed. Therapy with stress doses of corticosteroids should be initiated even before the confirmation of the diagnosis when there is a high index of suspicion. The side effects of a short course of high-dose corticosteroids in a critically ill patient are minor compared with the possible consequence of cardiovascular collapse and death.

KEY POINTS

- AI is a true emergency and requires rapid diagnosis.
- Common symptoms of AI include weakness, fatigue, and loss of appetite.
- The classic presentation of acute AI is a patient with unexplained hemodynamic instability who is unresponsive to intravascular volume resuscitation and use of vasopressors. AI can mimic cardiogenic, hypovolemic, or septic shock.
- Secondary AI is more common than primary AI. The most common cause of secondary AI is discontinuation of corticosteroid therapy.
- Patients who have taken 40 mg of prednisone per day or its equivalent for a period longer than 2 or 3 weeks during the past year should be considered to be adrenal insufficient until proved otherwise.
- Autoimmune disease is currently the most common cause of primary AI and accounts for approximately 80% of cases. The second most common cause of primary AI is adrenal gland destruction by *Mycobacterium tuberculosis*.
- Ketoconazole, phenytoin, phenobarbital, rifampin, and etomidate can cause AI.
- When there is a high suspicion of AI, hormonal testing is necessary to confirm the diagnosis.
- Therapy with stress doses of corticosteroids should be initiated even before the confirmation of the diagnosis when there is a high index of suspicion. The side effects of a short course of high-dose corticosteroids in a critically ill patient are minor compared with the possible consequence of cardiovascular collapse and death.

extranuclear effects that are especially important in cardiovascular physiology.² Transporters necessary for cellular uptake of thyroid hormone recently have been recognized.³ Thyroxine (T₄) acts as a prohormone for T₃ and itself is only weakly interactive with thyroid hormone receptors. The compound 3,3',5'-triiodothyronine (reverse T₃) is almost devoid of metabolic activity (Fig. 60.1).

Thyroid hormone exerts profound multisystemic actions. A patient developing clinically apparent thyroid dysfunction may experience some symptoms soon after onset, but a change of thyroid hormone availability is slow to exhibit its full effect. On the other hand, patients with established hyperthyroidism or hypothyroidism may destabilize quickly in response to intercurrent illness or medical and surgical interventions.

Thyroid hormone action is initiated by the binding of nuclear hormone receptors activated by 3,5,3'-triiodothyronine (T_3) to nuclear thyroid hormone response elements, in which the hormone-receptor complex acts as a transcription factor.¹ In addition, T_3 exerts rapid nontranscriptional

Normally about 80% of circulating T_3 and probably greater than 90% of circulating reverse T_3 are derived from circulating T_4 . Peripheral production of T_3 is modulated by the availability of T_4 , by peripheral cellular uptake of T_4 , and by the activities of the enzymes identified as iodothyronine selenodeiodinase 1 (D1), selenodeiodinase 2 (D2), and selenodeiodinase 3 (D3). The enzymes affecting peripheral levels of circulating thyroid hormone and tissue levels of T_3 either convert T_4 to T_3 , also removing reverse T_3 by deiodination (the D1 and D2 enzymes), or deiodinate and thus inactivate T_3 (the D3 enzyme) and convert T_4 to reverse T_3 (the D3 enzyme)^{4,5} (see Fig. 60.1).

Figure 60.1 Enzymatic conversion of iodothyronines by iodothyronine selenodeiodinase 1 (D1), iodothyronine selenodeiodinase 2 (D2), and iodothyronine selenodeiodinase 3 (D3). T_3 is the metabolically active hormone (3,5,3'-triiodothyronine). Reverse T_3 is metabolically inactive (3,3',5'-triiodothyronine). T_4 is converted to T_3 by the activating action of the D1 and D2 enzymes. Reverse T_3 is deiodinated by the D1 and D2 enzymes. T_3 is deiodinated and inactivated principally by the D3 enzyme. (Adapted with permission from Figure 1 of Bianco AC, Salvatore D, Gereben B, et al: Biochemistry, cellular and molecular biology, and physiological roles of the iodothyronine selenodeiodinases. *Endocr Rev* 2002;23:38-89.)

HORMONE TRANSPORT

Circulating T_4 is carried about 49% to 64% by thyroxine-binding globulin (TBG), 12% to 13% by transthyretin, and 7% to 9% by albumin. T_3 is carried 80% by TBG, 9% by transthyretin, and 11% by albumin.⁶ A small fraction is transported by lipoproteins. About 0.03% of circulating T_4 and 0.3% of T_3 is free or unbound. TBG is produced by the liver, and transthyretin by the liver and choroid plexus. The approximate half-lives of circulating transport proteins are transthyretin, 2 days; TBG, 5 days; and albumin, 15 days.⁶ Recent research suggests that TBG allows targeted delivery of T_4 to tissues, for example, at sites of inflammation.⁷ The unbound fraction of circulating hormone gains access to peripheral tissues and pituitary, determines metabolic status, and participates in feedback inhibition of the pituitary.

Unbound circulating hormone remains in a dynamic equilibrium with hormone provided by thyroid output, carried on transport proteins, or taken up or released by peripheral tissues. The half-life of circulating hormone is

about 1 week for T_4 and 1 day for T_3 . Deiodination occurs in many tissues, and the partially metabolized moieties are excreted in bile. Some enterohepatic recirculation occurs.

THYROID FUNCTION

Thyroid function is regulated by cyclic adenosine monophosphate (cAMP)-dependent events initiated by binding of thyroid-stimulating hormone (thyrotropin; TSH) to the thyroid follicular cell membrane TSH receptor. TSH stimulation leads to consumption of colloid and the release of thyroglobulin (TG), T_4 , T_3 , and reverse T_3 . Activation of the TSH receptor promotes conversion of T_4 to T_3 within the thyroid and proportionately increased secretion of T_3 by the thyroid. Thyroidal autoregulation is influenced by the availability of iodine.

PITUITARY AND HYPOTHALAMIC FUNCTION

Pituitary TSH and hypothalamic thyrotropin-releasing hormone (TRH) are ultimately necessary for regulation of

adequate thyroid hormonogenesis and thyroid hormone secretion. On the principle of feedback inhibition and in the absence of central disease, an inverse relationship between circulating levels of TSH and free T_4 is expected. The D2 enzyme in hypothalamic tanycytes in animal models is thought to be responsible for conversion of T_4 to T_3 , allowing for local regulation by hypothalamic tissue levels of T_3 , dependent upon not only circulating hormone levels but also local deiodinase activity.

DIAGNOSTIC APPROACH TO THYROID DISEASE

HISTORY, PHYSICAL EXAMINATION, AND RECORD REVIEW

In critical illness, ambiguity of thyroid function tests is commonplace. The obstacles to laboratory assessment augment the importance of record review, history, and physical examination. When overt thyroid dysfunction is present, the history and physical examination usually yield multisystemic positive findings.⁸

CASE FINDING BY SCREENING

Ambulatory patients who should be screened and periodically monitored for thyroid dysfunction include those with a history of previous thyroid surgery or radioactive iodine therapy; those with deterioration of cardiac function or weight loss; and those receiving lithium, amiodarone, α -interferon, interleukin 2 therapy, tyrosine kinase inhibitors, and other medications affecting thyroid function.

In a meta-analysis of earlier studies, the frequency of thyroid disease ascertainable by screening hospitalized patients was similar to that among outpatients, about 1% to 2%.⁹ In the hospital the relatively low case-finding rate and the confounding effect of nonthyroidal illness have been viewed as impediments to general screening of unselected patients, except possibly among elderly women.^{10,11} However, one study in which TSH and free T_4 index were performed on sera drawn at the time of admission from 364 consecutive patients suggested that the rate of nonthyroidal illness syndrome (7.4%) was exceeded by the combined rates of unsuspected thyroïdal failure (5.8%), subclinical hypothyroidism (6%), and hyperthyroidism (2%).¹² Among critical care patients, the case-finding rate for thyroid disease during screening is not known with confidence. Clinical suspicion of thyroid disease based on patient symptoms or findings should, of course, result in testing.

ASSAYS AND IMAGING

Among critically ill patients, the TSH assay taken alone may yield misleading results, and the utility of most commercial methods for determining free thyroid hormone levels is limited.¹³⁻¹⁷ Thyroid function test results may change on a daily basis. The best course of action is not to screen with a single test but to order a potentially useful battery of tests from the outset.

SIMULTANEITY OF SAMPLING OF TROPIC AND TARGET HORMONE

In normal health, the trophic hormone TSH and the circulating target gland thyroid hormones exhibit the characteristics of regulation by feedback inhibition. Thyroïdal autonomy or primary thyroïdal failure can be diagnosed if unambiguous reciprocal changes of TSH and target gland hormone are seen, each into the clearly abnormal range. In order to interpret the relationship between trophic and target hormones, it is essential that measurements of TSH and thyroid hormones, and any assessments of hormone binding, should be performed on samples of blood that were obtained simultaneously.

THYROID-STIMULATING HORMONE

Reasons for misleading TSH results, some of which apply to critically ill patients, include nonequilibrium conditions in which thyroid status has recently fluctuated, acute psychiatric illness, nonthyroïdal illness syndrome, central causes of hyperthyroidism or hypothyroidism, and the effects of medication.¹⁸⁻²⁰ The distribution of TSH results in nonthyroïdal illness syndrome may overlap with the range seen in thyrotoxicosis. Conversely, in mild cases of subclinical thyrotoxicosis, for example, in nodular thyroid disease at the earliest stages of autonomy, TSH suppression may be minimal. The indication for measuring TSH is to support a diagnosis of primary hypothyroidism or hyperthyroidism.

ESTIMATES OF FREE THYROXINE

Although with some exceptions most free T_4 assays perform well in the ambulatory setting, in critically ill patients some commercial assays for free T_4 yield low results that cannot be verified by an equilibrium dialysis method.^{14,17} The indication for ordering a free T_4 rather than total T_4 assay is to assess thyroid function in the presence of suspected abnormalities of thyroid hormone transport or to clarify the significance of an abnormal total T_4 result in a patient whose clinical condition appears euthyroid. A normal result of a free T_4 determination together with a normal TSH is reassuring.

FREE T_4 BY EQUILIBRIUM DIALYSIS OR ULTRAFILTRATION

High levels of free T_4 may occur in the early stages of sepsis (see discussion under "Nonthyroïdal Illness Syndrome"). By most assay methods, high estimates of free T_4 also may occur in the presence of acute elevations of free fatty acids or drugs including furosemide, heparin, or enoxaparin that directly or indirectly cause inhibition of T_4 binding to transport proteins, such that there actually is an *in vitro* elevation of free T_4 (see later discussion under "Medication Effects"). When elevation of free T_4 is caused by such effects, not only standard commercial assays but also free T_4 assays by equilibrium dialysis or ultrafiltration are likely to report an elevation of free T_4 .

A free T_4 assay by equilibrium dialysis or ultrafiltration may help resolve the meaning of a low estimation of free T_4 determined by other commercial methods. In critical care medicine the principal indication for ordering a free T_4

assay by equilibrium dialysis or ultrafiltration is the concern that other free T_4 methods might yield false low results.

TOTAL THYROXINE

In order to avoid risk of misinterpretation of free T_4 elevations, the total T_4 should be one of the front-line tests among patients treated with furosemide in high dosage, heparin, or enoxaparin. If the TSH and total T_4 both are normal, then the patient is probably euthyroid.

When the patient condition predicts that free T_4 methods may yield spurious low results, or when a free T_4 assay has yielded a low result in a patient having low or normal TSH, a confirming test to discount central hypothyroidism is desirable. The institutional turnaround time for a total T_4 assay may be faster than for the gold standard test, a free T_4 assay by equilibrium dialysis or ultrafiltration. The total T_4 may be measured, together with an estimate of binding by transport proteins.

The indication for ordering a total T_4 assay is to discount hyperthyroidism in the presence of misleading free T_4 elevations in euthyroid patients, to provide reassurance when considered together with an estimate of thyroid hormone binding that central hypothyroidism may be absent, or to demonstrate the presence and quantitate the severity of hypothyroidism or hyperthyroidism.¹³

T_3 UPTAKE OR THYROXINE-BINDING GLOBULIN AND CALCULATED FREE T_4 INDEX

The T_3 uptake, together with a determination of total T_4 , is used in index methods to provide information about hormone transport and to help estimate free T_4 . In critically ill patients with hypothyroxinemia, the free T_4 index frequently is misleading. Nevertheless, when hypothyroxinemia by a free hormone estimate is present but its interpretation is uncertain, for example, when the TSH is normal or low, it is advantageous to review a second independent assay such as the T_3 resin uptake or a direct measurement of TBG to see whether qualitatively the result is consistent with reduced T_4 binding sites on circulating transport proteins. Elevation of T_3 uptake accompanied by low total T_4 suggests reduced hormone binding to transport proteins, consistent with nonthyroidal illness syndrome. Nonelevated T_3 uptake or low T_3 resin uptake accompanied by hypothyroxinemia in the face of nonthyroidal illness suggests the possibility of hypothyroidism (Table 60.1).

Table 60.1 Use of Total T_4 and T_3 Uptake to Calculate Free Thyroxine Index (FTI)

	Total T_4	T_3 Uptake	Physiology Reflected by Test Results
Normal	Normal	Normal	Normal
Increased binding sites	↑	↓	Normal
Reduced binding sites	↓	↑	Normal
Hyperthyroid	↑	↑	↑
Hypothyroid	↓	↓	↓

T_3 , triiodothyronine; T_4 , thyroxine.

The index methods generally are inferior to the membrane dialysis or ultrafiltration methods of determining free T_4 , but the rapid turnaround time of the index method is advantageous. The combination of low T_4 with normal or low TSH may raise consideration of central hypothyroidism. The indication for an index method for free T_4 in this setting is to use the resin uptake or TBG measurement to provide qualitative evidence for a competing explanation for low T_4 , namely, that T_4 carriage by transport proteins may be reduced.

THYROXINE-BINDING GLOBULIN

The transport protein TBG can be directly measured, and the result can be used together with a determination of total T_4 as one method of calculating a free T_4 index. TBG levels are increased in hepatitis, hepatoma, and human immunodeficiency virus (HIV) infection. The indication for ordering a TBG or T_3 resin uptake for calculation of a free T_4 index is to provide qualitative information about the significance of a low total T_4 in a setting in which the commercial free T_4 assay is judged to be unreliable. The TBG may be used, together with the total T_4 , to help discount suspicion of central hypothyroidism.

TOTAL T_3

Like T_4 , the total T_3 is affected by alterations of binding to hormone transport proteins. Measurement of T_3 should not be employed to evaluate the possibility of hypothyroidism or to evaluate the significance of a low T_4 . Under intense TSH stimulation, the failing thyroid preferentially secretes T_3 rather than T_4 , so that patients with T_4 reduction due to primary hypothyroidism still may maintain normal T_3 levels. The main indication for measuring total T_3 is suspicion of T_3 toxicosis or hyperthyroidism in patients lacking hyperthyroxinemia. If the TSH is suppressed to less than 0.1 μ IU/mL but T_4 is normal, measurement of T_3 is necessary. T_3 also is measured to evaluate for amiodarone-induced thyrotoxicosis.

FREE T_3

Free T_3 sometimes is found to be normal among patients with nonthyroidal illness syndrome having low total T_3 , helping offset suspicion of secondary hypothyroidism due to organic pituitary or hypothalamic disease. Methodologic limitations in critically ill patients may result in variability of findings between assay systems. Chopra and colleagues reported that by direct equilibrium dialysis radioimmunoassay in nonthyroidal illness syndrome serum free T_3 concentration was normal in approximately 83% of patients with low total T_3 .²¹⁻²³ The indication for ordering the free T_3 test is to confirm or exclude T_3 toxicosis in patients suspected of having thyroid transport abnormalities, such that reliance upon total T_3 might be inappropriate. Free T_3 also may help identify amiodarone-induced thyrotoxicosis.

REVERSE T_3

If T_3 and T_4 are low, and if hypothyroidism is present, then the reverse T_3 may be low. In contrast, in nonthyroidal illness syndrome, even though the T_3 and T_4 may be low, the concentration of reverse T_3 potentially is high, but not invariably so. Slow laboratory turnaround and frequency of normal reverse T_3 results in nonthyroidal illness syndrome

limit the usefulness of reverse T_3 measurement. The indication for ordering reverse T_3 is to differentiate intrinsic hypothyroidism from nonthyroidal illness syndrome.

SERUM ALBUMIN

In some circumstances, opposite changes of albumin and TBG are seen, for example, in hepatitis. However, when low T_4 levels are present, a finding of concomitant hypoalbuminemia usually permits the caregiver tentatively to attribute the low T_4 results to reduction of circulating transport proteins, including TBG.

ANTITHYROID PEROXIDASE AND ANTITHYROGLOBULIN ANTIBODIES

In sufficient titer, positive antibodies strongly suggest autoimmune thyroid disease. In the critical care setting the principal indication for antithyroid antibody determination is to evaluate the significance of a modest TSH elevation.

THYROID-STIMULATING HORMONE RECEPTOR ANTIBODIES

A sensitive assay for TSH receptor antibodies may suggest the classification of hyperthyroidism as Graves' disease.

RADIOIODINE UPTAKE AND THYROID SCAN

The radioactive iodine uptake is a number, expressed as a percentage of uptake counted 24 hours after administration of a small dose of radioactive iodine, and the scan provides an image. The radioactive iodine uptake test helps differentiate low-uptake forms of hyperthyroidism (amiodarone- or iodine-induced thyrotoxicosis, thyroiditis, factitious hyperthyroidism, and others) from high-uptake forms of hyperthyroidism (Graves' disease, toxic adenoma, and toxic multinodular goiter). These tests often are postponed until 4 to 6 weeks after the last use of an iodinated contrast medium. The utility of the radioactive iodine uptake and thyroid scan is to identify the cause of hyperthyroidism to help decide between therapeutic alternatives.

ULTRASONOGRAPHY AND COMPUTED TOMOGRAPHY

Examination of the thoracic inlet in cases of large compressive goiters is best accomplished with computed tomography (CT). The indication for thyroid ultrasonography is to obtain information about the size, texture, vascularity, and nodularity of the thyroid and to evaluate other structures in the neck.

"BEST PANEL" FOR CRITICALLY ILL PATIENTS

For confirmation of a suspected diagnosis of thyroid dysfunction, a panel rather than a single test is recommended at the outset. The TSH should not be used as monoscreening in the hospital (Fig. 60.2). The initial "best panel" is whichever has the faster turnaround time or weekend availability, or both, at the laboratory used by the institution. The initial panel should include either a calculated free T_4 index (utilizing T_3 uptake or TBG together with total T_4) or a free T_4 estimate by any other method having rapid turnaround time, together with total T_4 and TSH. These initial panels will yield unambiguous results in most cases of critical illness that are caused or complicated by preexisting clinically

Figure 60.2 Frequency of observation of values of serum thyroid-stimulating hormone (TSH) in each of seven ranges among normal ambulatory patients (solid line) and in the hospital setting (dashed line). The observed frequency distribution spans a broader range of TSH values during hospitalization, partly because TSH suppression occurs during illness or consequent to administration of medications, and partly because TSH overshoot occurs during recovery. (Adapted with permission from Spencer C, Eigen A, Shen D, et al: Specificity of sensitive assays of thyrotropin (TSH) used to screen for thyroid disease in hospitalized patients. Clin Chem 1987;33(8):1391-1396.)

significant primary hypothyroidism or hyperthyroidism. Furthermore, the findings of normal TSH and normal or elevated free T_4 with normal total T_4 suggest euthyroidism. The isolated finding of free T_4 elevation may result from sepsis or the effects of furosemide, heparin or enoxaparin.

If clinical examination suggests hyperthyroidism and marked suppression of TSH is present, but if hyperthyroxinemia cannot be demonstrated, then the next step is to draw simultaneously TSH and total and free T_3 .

If the free T_4 and TSH considered as a hormone pair appear discordant (both values high or both values low), and if the explanation or management is not straightforward, a consultation should be obtained. However, in the setting of nonthyroidal illness, if low T_4 , low free T_4 estimate, and normal or low TSH are demonstrated during screening, to discount suspicion of secondary hypothyroidism it is sometimes helpful to order TSH, free T_4 by equilibrium dialysis, and morning cortisol (Box 60.1).

MEDICATION EFFECTS

When unexpected thyroid function test results are reported, a medication review should be conducted. Drugs may alter the results of thyroid function tests either in vivo or in vitro without affecting thyroid function. Additionally, drugs not designed to treat hypothyroidism or hyperthyroidism may

alter thyroid function.¹⁵⁻¹⁷ Periodic monitoring before and during long-term use should occur during use of a drug that is recognized to be a potential cause of thyroid dysfunction. Medication effects are summarized in Table 60.2.

Suppression of TSH is seen during use of dopaminergic drugs, glucocorticoids, and octreotide. High total T₄ can result from elevation of transport proteins, as seen during pregnancy or during treatment with estrogen, oral contraceptives, tamoxifen, raloxifene, 5-fluorouracil, and other medications, or resulting from hereditary or acquired disorders affecting hormone transport protein concentration, such as hepatitis. If the only abnormality is increased concentration of carrier proteins, then total T₄ will be high, but TSH will be normal and in an appropriate assay system the free T₄ will be normal.

Lowering of total T₄ may result from reduction of thyroid hormone transport protein concentration, as may be seen during treatment with glucocorticoids. Lowering of total T₄ may occur during use of drugs that cause displacement of thyroid hormone from binding proteins, as seen during treatment with salicylates and congeners, phenytoin, and carbamazepine. If the only abnormality is reduced concentration of carrier proteins, then TSH will be normal and in an appropriate assay system the free T₄ often will be normal. However, during use of drugs that may cause acute displacement of thyroid hormone from transport proteins, misleading elevations of free T₄ or free T₃ may occur. These drugs notably include furosemide and heparin, given subcutaneously or even given at the low doses used to flush intravenous lines, or enoxaparin. The lipoprotein lipase activity of heparin causes release of free fatty acids, which in turn

reduce thyroid hormone binding to transport proteins, resulting in elevation of free T₄.

Selective lowering of T₃ levels without reduction of T₄ levels may result from inhibition of peripheral conversion of T₄ to T₃, as may occur during use of glucocorticoids, beta blockers, iodinated cholecystographic contrast agents, and amiodarone.

TSH elevation signifying hypothyroidism or TSH suppression signifying hyperthyroidism may result, or patients may remain euthyroid during treatment with any of the following: interferon- α ,^{24,25} lithium,^{26,27} iodinated contrast agents,²⁸ iodine,²⁹ and amiodarone.³⁰⁻³⁵ During use of iodine-containing medications, hyperthyroidism of the Jod-Basedow type due to the iodine content of the drug may fail to self-resolve. However, when the mechanism of hyperthyroidism is destructive thyroiditis, as may be seen during some cases of interferon- α -induced hyperthyroidism and type 2 amiodarone-induced thyrotoxicosis, a possible sequence is hyperthyroidism followed by hypothyroidism.^{31,32} The prevalence of amiodarone-induced hypothyroidism has been variably reported, but it may be seen in up to 22% of treated patients from iodine-sufficient regions,³⁵ and its occurrence may be increased in the presence of positive antithyroid antibodies.^{30,33} The combined findings of elevation of total and free T₄ together with reduction of T₃ occur in euthyroid persons receiving amiodarone; these findings taken alone, when seen together with a normal TSH, do not indicate thyroid dysfunction

Figure 60.3 Nonthyroidal illness syndrome. The time course of concentration of circulating iodothyronine levels are shown qualitatively during evolution of nonthyroidal illness syndrome. A characteristic sequence involves first the development of a low total T_3 , initially with normal T_4 or sometimes with high free T_4 . Characteristically, as T_3 falls, reverse T_3 (RT_3) rises. With duration of illness, as thyroid hormone transport protein concentrations decline, concentrations of total T_3 and total T_4 (TT_4) both are affected, and total T_4 levels fall. Later, during the greatest severity of the illness, there may be low thyroid-stimulating hormone (TSH) and low free T_4 , a predictor of higher mortality risk. During recovery, TSH overshoots the normal range (not shown) as T_4 rises. Finally, after recovery, tests become normal. (Adapted with permission from Figure 1⁵⁶; In turn, Chopra had reproduced this from Nicoloff et al.)

(Box 60.2). High TSH signifying hypothyroidism may be caused by tyrosine kinase inhibitors including sunitinib, imatinib, motesanib, and sorafenib.³⁶⁻⁴¹

NONTHYROIDAL ILLNESS SYNDROME

Nonthyroidal illness syndrome is usually recognized as a constellation of laboratory findings of uncertain clinical significance, discovered on thyroid function testing among patients having acute medical or surgical illness, the more pronounced abnormalities being associated with worse

prognosis, and characterized by resolution after recovery from illness (Fig. 60.3). Although the severity of illness often makes clinical assessment difficult, patients usually appear clinically euthyroid. Laboratory findings of nonthyroidal illness syndrome may occur with psychiatric illness, starvation, congestive heart failure, acute and chronic renal failure, acquired immunodeficiency syndrome (AIDS), postoperative status, trauma, and in general with critical illness.^{19,42-62}

High free T_4 without elevation of total T_4 , seen in the early stages of nonthyroidal illness, may be associated with use of certain drugs or with sepsis. Otherwise, during development of nonthyroidal illness syndrome, reduction of circulating T_3 is one of the earliest and most consistently observed findings, possibly seen in over 70% of patients, depending upon the duration and severity of the illness.^{42,43} The decline of T_3 often is accompanied by a rise of reverse T_3 . Patients with chronic renal failure who have low T_3 do not invariably have high reverse T_3 levels,^{44,45} and patients with HIV may have low reverse T_3 .⁵²

The additional finding of a low T_4 together with low T_3 , a combination not usually seen at the onset, suggests nonthyroidal illness syndrome of greater severity and duration. Some cases of low total T_4 during the subacute stage of nonthyroidal illness are caused by transport protein deficiency alone, not necessarily accompanied by decline of free T_4 , whereas others may result from TSH suppression. Not all patients experience progression to the stage of TSH suppression. If the free T_4 , as evaluated by equilibrium dialysis, is low at the same time that TSH is low, biochemical differentiation between nonthyroidal illness syndrome and central hypothyroidism due to pituitary or hypothalamic disease is often not possible. In fact, nonthyroidal illness syndrome may be a cause of functional central hypothyroidism.

During recovery from nonthyroidal illness the TSH often is mildly elevated above the normal ambulatory reference range, and the free T_4 is normal. The differential diagnosis includes subclinical primary hypothyroidism. After recovery from nonthyroidal illness syndrome, thyroid function tests are normal. There are of course exceptions to the described sequence. Not all of the findings are seen in every case.

INCIDENCE

Among hospitalized patients, intrinsic thyroid disease is less common than nonthyroidal illness syndrome.^{9,11,47} The prevalence of nonthyroidal illness syndrome among patients with psychiatric disease has been reported to be about 10%, often manifesting as elevated TSH or elevated T_4 .^{19,55} Abnormalities of thyroid function tests interpreted as euthyroid sick syndrome were found in 51.5% of elderly patients undergoing emergency surgery.⁵⁷ Hypothyroxinemia without TSH elevation was reported in 22% of critically ill patients in one study.⁴⁶ In another study of intensive care unit patients, depending upon the duration of illness and patient outcome, the findings of low total T_3 approached 70% to 80%, and about half of patients had low total T_4 .⁵⁹

PATHOGENESIS OF THE LABORATORY FINDINGS

The laboratory findings of nonthyroidal illness have been recognized for years, but the understanding of the

pathogenesis of the findings has undergone rapid evolution in recent years, accompanied by controversy on the relative importance of each of several mechanisms in producing the observed features.

In order to understand the mechanisms for observed alterations of iodothyronine molecules (T_4 , T_3 , and reverse T_3) during nonthyroidal illness, under conditions of health and illness with and without specific interventions, there would need to be comparative human data on each of the following: tissue-specific functions of thyroid hormone; actual tissue levels of T_4 and T_3 ; cellular uptake of thyroid hormones; activity of each of the deiodinase enzymes in each tissue of interest, including hypothalamus and pituitary, thyroid, liver, muscle, and other tissues; tissue-specific direct and indirect mechanisms of regulation of each deiodinase enzyme, including enzyme-regulating effects of iodothyronines, cytokines, and drugs; contribution of each tissue and each of the three deiodinase enzymes to circulating levels of T_3 ; the role of transport proteins in targeted delivery of thyroid hormone in health if any and in illness; and any adaptative or maladaptative effects of the alterations of iodothyronine availability seen in illness. Much of our present knowledge derives from experimental animal models and is complicated by possible ambiguity of experimental assay results for deiodinase enzyme activity and by the necessarily inferential nature of human data.^{5,7,63-96}

Alterations of T_3 and reverse T_3 usually precede reductions of T_4 . Peripherally, there is reduced production of T_3 by 5'-deiodination of T_4 , reduced removal of reverse T_3 by 5'-deiodination, and increased removal of T_3 by deiodination (see Fig. 60.1). The reduction in circulating T_3 is believed to result from a combination of mechanisms, including changes of cellular uptake of T_4 , reduced activity of deiodinase enzymes that normally catalyze peripheral conversion of T_4 to T_3 , inactivation of T_3 by deiodination resulting from activity of the D3 enzyme, and possibly decline of hypothalamic TRH resulting from an enzymatically mediated increase of T_3 production in the tanycytes.⁵ The role of cytokines in mediating some of these changes has been explored.^{71,76-79,81,84} Because T_3 may amplify its own production at the tissue level by activating the D2 enzyme, a decline of central TSH drive to the thyroid indirectly could reduce peripheral production of T_3 . With acknowledgment that the finding of free T_3 abnormalities may be method-dependent, studies suggest that in some but not all patients having low total T_3 , the results of free T_3 assays may be normal.²¹⁻²³

Elevations of free T_4 sometimes occur in nonthyroidal illness, often accompanied by low or low normal total T_4 , and without TSH suppression. The isolated finding of free T_4 elevation in vivo at least in some instances may represent artifact, such as could be introduced by nonselective beta blockers, furosemide, or free fatty acids (see previously, under "Assays and Imaging"). Mechanisms leading to high free T_4 in the early stages of sepsis have been controversial. Circulating inhibitors of binding of T_4 to transport proteins may be present such as nonesterified fatty acids.^{65,67-69,72} Additionally, cleavage by elastases or consumption of the TBG molecule by serine proteases may occur at sites of inflammation, possibly leading to release of free T_4 to the circulation and permitting targeted delivery of T_4 at sites of inflammation.^{82,83,85}

Patients with both low T_4 and low T_3 generally have disease of greater severity and longer duration. Early studies of hormone kinetics in the setting of low T_4 were consistent with reduced binding to vascular sites.^{64,66} A low serum albumin level often, but not always, permits the caregiver to predict that TBG will be low. Hypoalbuminemia is highly associated with nonthyroidal illness syndrome.^{57,60} Reduced concentration of transport proteins is a prevalent finding among cases of nonthyroidal illness presenting with low T_4 and low T_3 .⁴⁹ Inhibitors of hormone binding to transport proteins also may result in low total concentrations of circulating thyroid hormone.

With use of an assay having low risk of artifact, most patients including those with low total T_4 have normal free T_4 . However, low free T_4 also may be demonstrated among other patients with nonthyroidal illness syndrome. The question of the true levels of circulating free T_4 remains unresolved, dogged by issues of assay artifact and heterogeneity within the patient population.

The more severely ill patients with nonthyroidal illness syndrome, usually those having low T_4 levels, as well as low T_3 , may have low circulating levels of TSH.^{51,80,81,87,88} Central production of TRH and TSH may be reduced by inflammatory mediators. In a human autopsy study, reduced TRH gene expression was demonstrated among patients with an antemortem finding of low T_3 .⁸⁰ In animal studies, it has been suggested that central conversion of T_4 to the active hormone T_3 in hypothalamic tanycytes under the action of the D2 enzyme, by producing local hyperthyroidism under conditions of illness, may act as a negative feedback signal that reduces hypothalamic release of TRH and pituitary release of TSH.^{5,88,92,94,96} Therefore, in prolonged or severe nonthyroidal illness syndrome, a central mechanism may contribute to the findings of low T_4 and low T_3 .

Investigationally, after TNF- α administration, as during recovery following nonthyroidal illness, there may be temporary overshoot of TSH into the mildly elevated range, accompanied by rising T_4 .^{51,81}

Presently it is unknown whether nonthyroidal illness syndrome is adaptive or maladaptive. In starvation, low T_3 syndrome may promote protein sparing.⁹⁷ Human trials have not been conducted with a sufficient number of randomized, critically ill human subjects to resolve the question of whether thyroid hormone therapy is beneficial. In a non-randomized study of patients with sepsis, T_3 was used to reduce dopamine dependence.⁹⁸ Treatment with T_3 for human burn injury showed no benefit.⁹⁹ In a small study of critically ill patients with low T_3 and low T_4 , therapy with T_4 did not correct the low T_3 or improve the prognosis,¹⁰⁰ and T_4 for nonthyroidal illness may increase mortality rate among acute renal failure patients.¹⁰¹

NONTHYROIDAL ILLNESS SYNDROME AMONG CARDIAC PATIENTS

Low T_3 or low T_3 and T_4 levels are observed in the setting of advanced heart failure, after revascularization, and after myocardial infarction, providing a rationale for therapeutic trials of treatment with thyroid hormone among cardiac patients.¹⁰²⁻¹²¹ Among patients with severely impaired left ventricular performance, the use of intravenous T_3 as an

alternative to standard therapy (such as dopamine) and the compatibility or usefulness of T_3 in combination with other inotropic and vasodilating regimens requires further research. Correction of any reversible ischemia should first be achieved. Use of intravenous T_3 shows promise as an inotrope and vasodilator.^{104,111} In the setting of advanced heart failure, coronary bypass or valve surgery, correction of congenital heart lesions, or in the treatment of transplantation donors and recipients, the benefits that have been attributed to intravenous T_3 therapy include improvement of cardiac index with reduction of systemic vascular resistance,^{104,111} a reduction in postoperative episodes of atrial fibrillation,¹⁰⁷ reduction in estimated mortality rate among high-risk patients,¹⁰⁹ a reduced requirement for inotropic support and mechanical devices,^{112,113} a lower incidence of postoperative myocardial ischemia,¹¹³ improved cardiac allograft function,¹⁰² and improved neuroendocrine profile with improved ventricular performance.¹²¹ Whether the apparently beneficial cardiac effects of T_3 administration are pharmacologic effects or at least partially the effects of physiologic replacement of a true hormone deficiency are unclear. Overall, the use of T_3 for cardiac indications has not gained widespread acceptance.

APPROACH TO MANAGEMENT AND THERAPEUTIC ALTERNATIVES

It is unknown whether the spontaneously developing alterations of tissue exposure to thyroid hormone during nonthyroidal illness are advantageous or disadvantageous to the patient. Although there is interest in evaluating T_3 therapy for nonthyroidal illness syndrome, it is expected that differences in outcome resulting from such treatment will be small and difficult to demonstrate.^{62,122-125} Proposed approaches have not been adequately studied for safety or efficacy in critically ill patients having nonthyroidal illness syndrome. A special niche may exist for the use of T_3 in the treatment of cardiac patients who require hemodynamic support. As a precaution, it is noted that high levels of T_3 have been identified as a risk factor for coronary events.¹²⁶ Although future research may bring about changes in the standard of care, at the present time for nonthyroidal illness syndrome most experts recommend observation without thyroid hormone treatment, with reevaluation of thyroid function tests after recovery. The philosophy of nontreatment would imply that there is no obligation to order thyroid tests unless thyroid disease is suspected.

Treatment for possible hypopituitarism is offered when caregivers believe the clinical evaluation and results of thyroid tests do not permit exclusion of intrinsic disease of the thyroid, pituitary, or hypothalamus. If the patient is euthyroid and free of reversible myocardial ischemia and if adequacy of cortisol production is assured by measurement or by concomitant administration, then treatment with thyroid hormone will probably do no harm.

IMPLICATION FOR PROGNOSIS

Normal T_3 is a favorable prognostic indicator, whereas the biochemical findings of low T_3 or other findings of nonthyroidal illness syndrome predict worse outcomes of critical illness in general.^{46,110,118,127-140}

HYPOTHYROIDISM AND MYXEDEMA COMA

HYPOTHYROIDISM

Common causes of hypothyroidism include autoimmune destruction (Hashimoto's thyroiditis) or previous surgery or radioiodine ablation therapy for hyperthyroidism, as well as medication-induced causes. Patients with anti-thyroid antibodies may be at special risk of iodine- or amiodarone-induced hypothyroidism. The manifestations of hypothyroidism are dependent not only on the severity of hormone deficiency by laboratory testing but also the duration of hypothyroidism.

INCIDENCE

In contrast to the high frequency of finding the laboratory manifestations of nonthyroidal illness syndrome in the intensive care unit, among outpatients the prevalence of spontaneous hypothyroidism is relatively low, found in 1% to 2% in iodine-replete communities, and more commonly found in women than in men.¹⁴¹⁻¹⁴³ An age-related increase of incidence of hypothyroidism exists, and the prevalence is higher in women. The appearance of overt hypothyroidism is predicted by prior isolated TSH elevation and positive antithyroid antibodies. Hypothyroidism can be induced by iodine, amiodarone, lithium, or tyrosine kinase inhibitors.

PATHOPHYSIOLOGY

Patients with severe hypothyroidism have reduced calorogenesis and oxygen consumption. Many metabolic processes proceed at a markedly reduced rate. Glycosaminoglycan metabolism is impeded, resulting in widespread tissue deposition of hyaluronan (hyaluronic acid). A contributory factor in the production of generalized edema is transcapillary albumin escape.¹⁴⁴ Slowing of the metabolism of lipoproteins results in secondary hyperlipidemia. Hypercholesterolemia is common. Hypometabolism affects conversion of carotene to vitamin A and the rate of removal of vitamin K.

Reduced ventilatory responses to hypoxia and hypercapnia appear to have a dominantly central mechanism, and there may be upper airway obstruction.¹⁴⁵⁻¹⁵⁰ The effusions of myxedema contain high concentrations of protein and cholesterol. Pericardial effusion is more characteristic than pericardial tamponade.¹⁵¹⁻¹⁵⁴ Vasoconstriction with or without hypertension exists. The mechanisms of resistance to catecholamine effects are complex and controversial. There is reduced responsiveness to adrenergic stimuli but actual elevation of circulating norepinephrine concentration.¹⁵⁵⁻¹⁵⁷ Myocardial contractility, oxygen consumption, ejection time, diastolic ventricular compliance, stroke volume, heart rate, and cardiac index are reduced and systemic vascular resistance is increased.^{115,119,120} The left ventricular end-diastolic pressure is not necessarily elevated in myxedema and the cardiac index may increase in response to exercise.¹⁵⁸⁻¹⁶¹ Nevertheless, when TSH is higher than 10 $\mu\text{IU/mL}$, there is an increased risk for congestive heart failure even at the stage of subclinical hypothyroidism.¹⁶²⁻¹⁶⁴ An increased occurrence of coronary artery disease also may exist.¹⁶⁵⁻¹⁷⁰ Hypomotility of the bowels is common. There

may be coexistent iron losses as a result of menorrhagia or gastrointestinal bleeding. Malabsorption of vitamin B₁₂ and folic acid may occur. A reduction in atrial natriuretic factor production may occur,¹⁷¹ as well as a reduction of the glomerular filtration rate. The kidney cannot excrete a water load effectively, but antidiuretic hormone deficiency cannot be consistently implicated when hyponatremia and defective intrarenal mechanisms are suspected.¹⁷²⁻¹⁷⁴ Calcium loading can result in hypercalcemia. Hyperuricemia commonly results from underexcretion of uric acid. Pituitary overproduction of prolactin but retarded responsiveness of the pituitary-adrenal axis to appropriate challenges may occur in myxedema.

CLINICAL MANIFESTATIONS

An adult patient with longstanding hypothyroidism will have multisystemic findings. Constitutional symptoms include cold intolerance, fatigue, constipation, and weight gain, the latter not invariably observed and usually modest. Dry, brittle hair may be noted. Sleep apnea may occur. Women may have galactorrhea or menorrhagia. Myopathic and arthritic complaints can lead to misdiagnosis of a primary rheumatic disorder. Patients may have carpal tunnel syndrome. A history of somnolence, dementia, syncope, or seizures may exist.

Hypertension may be attributable to myxedema. The thyroid is often atrophic but may be goitrous. The following characteristics often permit clinical diagnosis: a deep, husky quality of the voice; slow mode of speech; involuntary blepharoptosis; torpid expression; facial bloating; eyelid and infraorbital edema; sallowness, facial pallor; hearing loss; bradycardia, distant muffled heart tones; cool, dry, coarse skin; nonpitting edema of the supraclavicular fossae, hands, legs, and feet¹⁴⁴; bruising; and the delayed relaxation of deep tendon reflexes. The patient may present with adynamic ileus.

Despite the reduction of glomerular filtration rate, the serum creatinine and blood urea nitrogen (BUN) are normal. Macrocytic anemia may be present with or without vitamin B₁₂ deficiency, and iron deficiency is common. The erythrocyte sedimentation rate is modestly elevated. Elevation of muscle enzymes is seen in advanced cases. Unless a creatine kinase (CK) is measured, abnormal aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels of muscle origin may be misinterpreted as representative of liver dysfunction. An electrocardiogram (ECG) may show sinus bradycardia, first-degree atrioventricular (AV) block, low voltage QRS complexes, and nonspecific T-wave changes.

DIAGNOSTIC APPROACH

The TSH level of patients with untreated primary hypothyroidism can be lowered into the normal range by critical illness, but only rarely.¹⁷⁵ Sometimes the severity of TSH elevation is blunted by the myxedema itself, with extreme hypothyroxinemia accompanied by TSH levels that are elevated but may be less than 20 μ U/mL. In most cases of advanced hypothyroidism the TSH will be above the normal reference range and the T₄ and free T₄ will be low. Therefore, in general, during nonthyroidal illness the laboratory diagnosis of coexistent primary hypothyroidism is straightforward (see Fig. 60.2).

Milder cases of hypothyroidism potentially can be confused with the recovery phase of nonthyroidal illness syndrome, when transitory TSH elevation commonly occurs. The patient should be examined for goiter. The finding of subnormal free T₄, positive antithyroid peroxidase antibodies, or TSH above 20 μ U/mL sometimes signifies intrinsic thyroid disease.^{18,51} Outpatient reassessment should occur.

In critically ill patients the diagnosis of secondary hypothyroidism is not straightforward. When a low free T₄ level by equilibrium dialysis and low TSH level are present, the question arises of whether the findings signify central hypothyroidism for any reason other than nonthyroidal illness syndrome. The most pressing immediate need would be to recognize and treat cortisol deficiency or pituitary mass effect. History of prior reproductive dysfunction, examination of cranial nerve function and mental status, and measurements of cortisol and other pituitary and target gland hormones, including follicle-stimulating hormone (FSH) and luteinizing hormone (LH) among postmenopausal women, may suggest preexisting pituitary dysfunction with or without tumor or the new occurrence of pituitary apoplexy or may help provide evidence of intactness of pituitary function. However, some critically ill patients lacking intrinsic hypothalamic or pituitary disease may have features of “eugonadal sick” syndrome as well as nonthyroidal illness syndrome. Measurement of cortisol or free cortisol may be of special value.⁵⁴ The diagnosis of pituitary tumor or apoplexy is confirmed by pituitary magnetic resonance imaging (MRI) or CT scanning.

APPROACH TO MANAGEMENT

Replacement therapy for hypothyroidism can be provided as levothyroxine (thyroxine, T₄) or liothyronine (triiodothyronine, T₃), each of which is available for oral or intravenous administration, but T₄ is the preferred hormone for the treatment of ambulatory patients and most hospitalized patients.¹⁷⁶⁻¹⁹¹ Normally, production of T₃ from T₄ occurs rapidly. Because of the prolonged half-life of T₄, after each daily dose or after short-term interruption of chronic T₄ therapy there are stable blood levels of T₄ and T₃.^{178,179} An ambulatory hypothyroid patient, when treated with T₄ in dosage sufficient to maintain euthyroidism (normal TSH), often has normal T₃ but blood levels of T₄ slightly above the mean for a euthyroid patient.¹⁸³ A patient whose T₄ dose requirement was established before hospitalization generally should be maintained on the same dose, if it can be given orally. The oral absorption of T₄ is impeded by intestinal disease or concomitant administration of iron, sucralfate, cholestyramine, colestipol, calcium, and other drugs.¹⁸⁵ Enteric administration of T₄ should be separated from these drugs by at least 2 to 4 hours.

When T₄ therapy is given for overt hypothyroidism, whole body oxygen consumption and myocardial work load increase. If coronary artery disease is present, the myocardial demand for increased oxygen consumption may not be met. The risks of angina, arrhythmia, or myocardial infarction indicate the need that introduction of thyroid hormone treatment of older patients should be cautious and gradual, using starting doses less than full replacement, making incremental small doses until full replacement is achieved by biochemical parameters, with assessment of tolerance before each adjustment, and with willingness to aim for less

than full replacement in case of poor tolerance. Despite the need for a cautious approach in patients who may have heart disease, the long-range goal is to reduce risk for dyslipidemia, heart failure, and coronary atherosclerosis.¹⁹²⁻¹⁹⁸ Even younger patients sometimes may experience discomfort if replacement is introduced too quickly, experiencing myopathic symptoms that may worsen at first but eventually will resolve if treatment continues, or, rarely, cardiac symptoms.¹⁹⁸ In case of intolerance during initiation, the risk for abandonment of treatment may be reduced if a temporary T_4 dose reduction is made, with intent to work back more gradually toward full replacement. An uncommon outcome during initiation of treatment in children is increased pseudotumor cerebri.

To initiate therapy for overt hypothyroidism, patients with abrupt development of hypothyroidism or young patients may be started on full replacement doses of T_4 . To reduce the risk of discomfort during initiation, young patients with longstanding severe untreated hypothyroidism may be started at a dose of levothyroxine 0.05 mg/day. Older patients or those with coronary artery disease should start with levothyroxine 0.025 mg/day. Increments of levothyroxine 0.0125 to 0.025 mg for older patients are made at about 3-week intervals until it is estimated that the patient is close to full replacement, and then the free T_4 and TSH levels are rechecked. After a dosage adjustment of T_4 therapy, 6 weeks is necessary before biochemical reevaluation will reflect a steady-state condition. After upward titration of the dose, the average adult requirement for hypothyroidism is about 0.112 mg/day levothyroxine orally. For elderly patients the dose is lower than for younger patients,^{180,183} and for subclinical or early hypothyroidism, the dose of levothyroxine necessary to normalize the TSH may be as low as 0.05 to 0.075 mg/day.

It may be stated anecdotally that atrial arrhythmias are no contraindication to providing replacement therapy for hypothyroidism.¹⁹⁵ Development of hypothyroidism during lithium or amiodarone therapy does not require drug discontinuation but may require thyroid hormone replacement.

Subclinical hypothyroidism refers to persistent TSH elevation with normal free T_4 and absence of characteristic symptoms of hypothyroidism. Mild or subclinical hypothyroidism is not likely to present short-term risks to a critically ill patient. However, evidence suggests increased long-term morbidity, including heart failure, from untreated subclinical hypothyroidism.^{162,164} Therefore, follow-up in the ambulatory setting is appropriate to determine whether TSH elevation is persistent.

The hypothyroidism associated with medication use may remit if the initiating agent is later withdrawn, so that determination of a treatment plan for hypothyroidism in part depends upon the drug and in part depends upon the severity of symptoms and duration of intended treatment with the drug held responsible for the development of hypothyroidism (Fig. 60.4).

Continuation of Established Thyroid Hormone Therapy During NPO Status

For prolonged NPO (nil per os, nothing by mouth) status or during continuous administration of substances that may impair absorption of levothyroxine or for other indications,

intravenous levothyroxine may be provided daily to substitute for enteral administration, in reduced amount compared to the ambulatory daily dose, with subsequent monitoring.* The fractional gastrointestinal absorption of a tablet of levothyroxine has been reported to be about 81%, considerably higher than the earlier estimate of 48%.¹⁸³ However, concomitant administration of other substances, including calcium carbonate, may diminish absorption.¹⁸⁶ Intestinal malabsorption and, anecdotally, development of severe right-sided heart failure may result in unusually high dose requirements for oral levothyroxine therapy. More than half of patients receiving enteral levothyroxine may develop subclinical or overt hypothyroidism after 2 to 3 weeks if a previously established levothyroxine dose is maintained concomitantly with continuous enteral feedings.¹⁸⁹ Owing to the long half-life of levothyroxine and delayed tissue response to dosage adjustments, manifestations of myxedema evolve only slowly after interruption of therapy, so that interruption of levothyroxine during short-term NPO status generally is inconsequential. The American Association of Clinical Endocrinologists and the American Thyroid Association (AAACE-ATA) guideline recommends that "Patients resuming L-thyroxine therapy after interruption (less than 6 weeks) and without an intercurrent cardiac event or marked weight loss may resume their previously employed full replacement doses."¹⁹¹ For patients whose oral intake will be curtailed for a prolonged interval, the usual enteral dose of levothyroxine should be reduced by 20% to 40% to arrive at a dose for intravenous therapy.^{176,183,188}

Precautions in the Care of the Hypothyroid Patient and Sensitivity to Pharmacologic Agents

The patient who has not yet been rendered euthyroid by therapy is at risk of water intoxication by overly vigorous intravenous fluid administration. There is risk of oversedation and central nervous system (CNS) suppression from sedative and analgesic drugs, which are metabolized and excreted abnormally slowly in the presence of hypothyroidism. The slow metabolism of drugs contributes to the marked propensity of hypothyroid patients to experience the effects of overdosage, especially with respect to digoxin, narcotics, sedatives, and analgesics. These drugs and digitalis should be given with caution, in reduced dosage. Perhaps because of reduced clearance of vitamin K, however, there is resistance to warfarin. Warfarin sensitivity may increase during treatment.

Preparation of the Patient with Untreated Hypothyroidism for Emergency Surgery or Coronary Revascularization

Subclinical hypothyroidism has not been shown to increase operative risk.²⁰⁰ For patients with overt hypothyroidism, there is increased risk of perioperative complications such as sensitivity to analgesics and anesthesia, prolonged ventilator dependence, hypotension, water intoxication, and iatrogenic myxedema coma. Elective surgery should be deferred until euthyroidism is attained. For emergency surgery, younger patients without coronary disease should be prepared as if they already had myxedema coma, using a

*See References 176, 183, 185-187, 189, 190, 199.

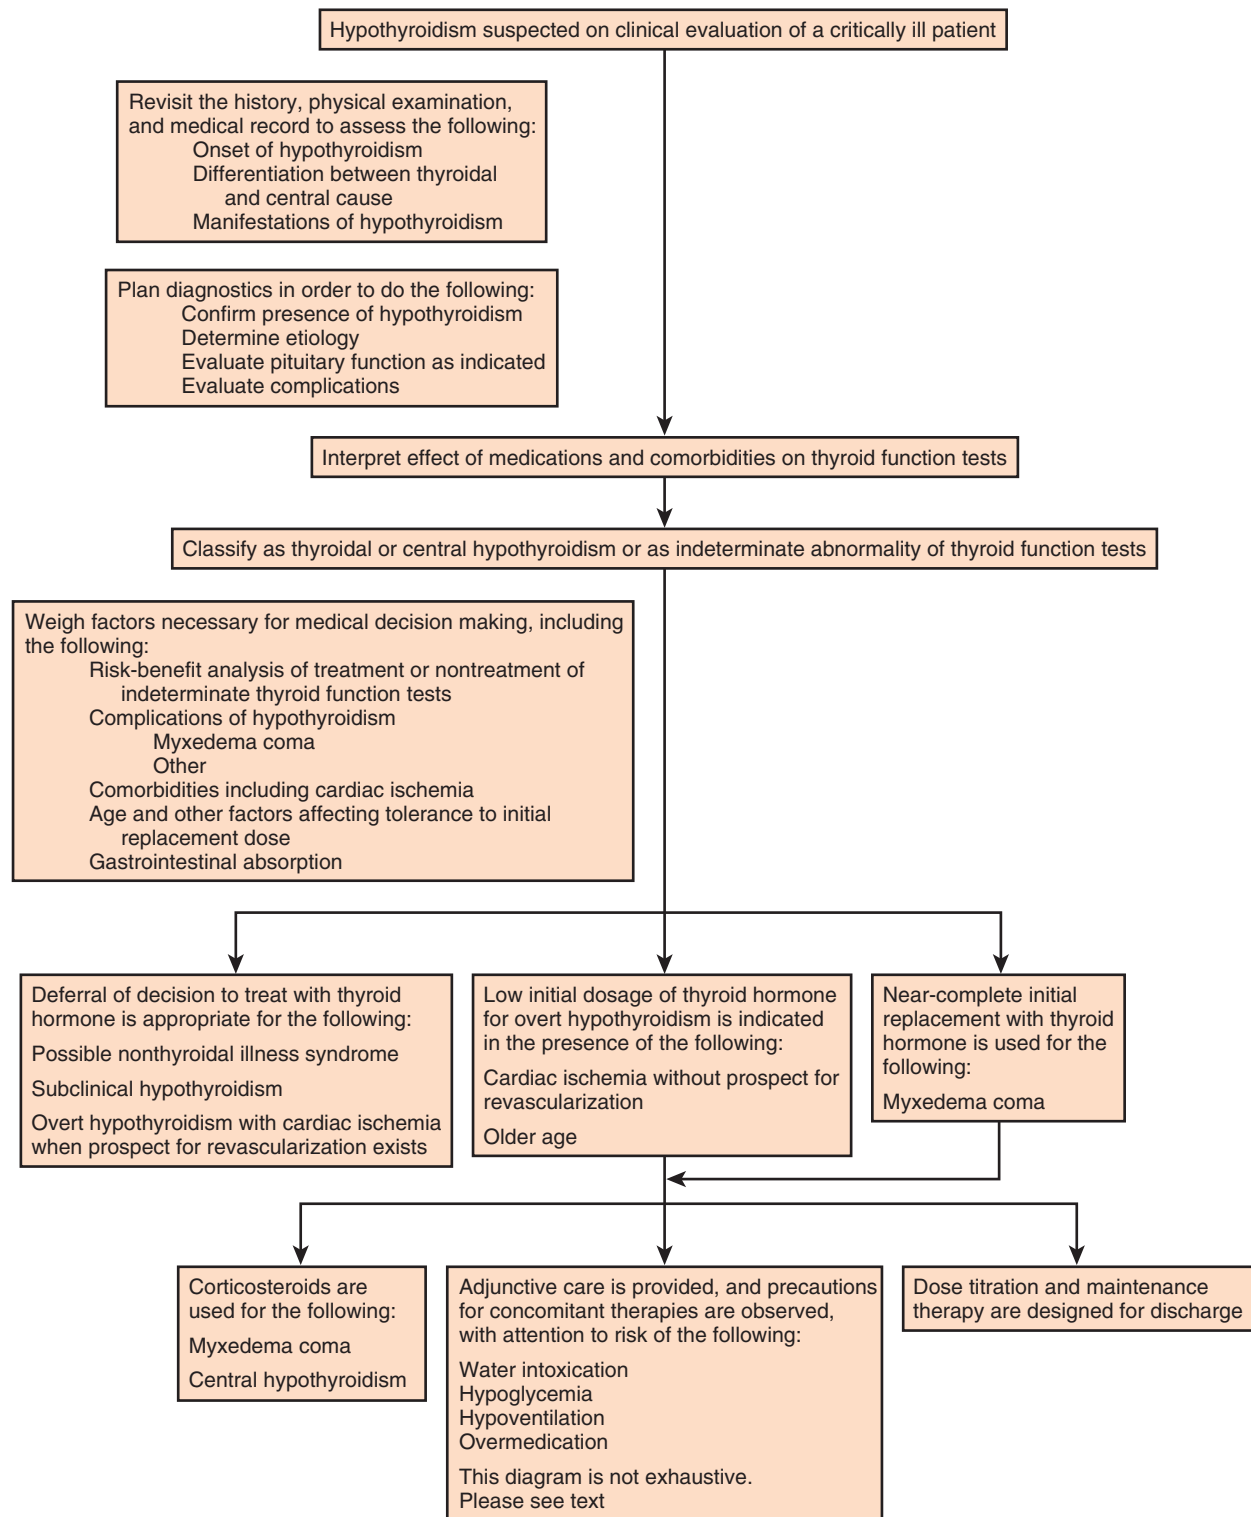

Figure 60.4 Approach to management for hypothyroidism.

preoperative intravenous bolus of levothyroxine, depending on age and transport protein status, as described later (see “Myxedema Coma”), and providing hydrocortisone coverage, with other precautions as described earlier (see “Precautions in the Care of the Hypothyroid Patient”). The risk of undiagnosed coronary insufficiency has to be considered in determining the preoperative levothyroxine replacement

regimen of older patients. Emergency surgery should be deferred for 24 to 48 hours after initiation of thyroid hormone treatment if possible.^{188,201,202}

Patients who are candidates for correction of reversible myocardial ischemia generally should undergo revascularization before one attempts to treat their hypothyroidism. The risks of immediate thyroid hormone replacement

before noncardiac surgery should be weighed against the probably acceptable risks of successful operation without levothyroxine pretreatment.^{188,194,203-212}

A protocol for patients with correctable coronary artery disease, or for others having surgery despite incompletely corrected hypothyroidism, might be to use light preoperative analgesia and sedation, avoid water intoxication, administer glucose as small volumes of concentrated dextrose solutions, be prepared to support ventilation for prolonged intervals postoperatively, provide hydrocortisone 100 mg starting immediately preoperatively and every 8 hours on the first postoperative day, taper and discontinue hydrocortisone over 5 to 7 days, and for those not yet treated, to initiate intravenous levothyroxine 0.05 mg daily in the immediate postoperative period.

PROGNOSIS

New onset of angina, myocardial infarction, or sudden death may occur within days or weeks after initiation of treatment for hypothyroidism.^{192,193} Secondary hyperlipidemia and most clinical manifestations of juvenile hypothyroidism and adult myxedema are reversible after therapy, although some features, such as anemia, may require months for correction.

MYXEDEMA COMA

HISTORY AND INCIDENCE

Our present-day knowledge of myxedema coma derives from isolated case reports and small retrospective series.²¹³⁻²³⁴ Historically, the low doses of thyroid hormone normally used to initiate treatment of uncomplicated hypothyroidism, when administered enterally for myxedema coma, failed to prevent fatalities. The mortality rate was probably higher than 80%. In 1964 it was demonstrated that intravenous replacement with 500 µg levothyroxine, a dose calculated to nearly replete body stores of T₄, improved the rate of survival.²¹⁸ Liothyronine (triiodothyronine, T₃) for intravenous injection later became commercially available.

PATHOGENESIS

Myxedema coma arising in the community can generally be divided into episodes that arise spontaneously and those that arise in connection with a precipitating illness or event. Those arising spontaneously tend to occur during the colder months of the year. Precipitating factors may include congestive heart failure, pneumonia or other infection, bleeding, administration of hypotonic fluids, sedative and analgesic drugs, or anesthesia and surgery. The particular risk of hypoventilation probably is increased by the presence of heart failure, obesity, pleural or other restrictive disease, chronic obstructive lung disease, neuromuscular disease, or exposure to drugs that reduce respiratory drive.^{146,147}

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Myxedema coma presents with a constellation of findings including physical evidence of advanced hypothyroidism, stupor, bradycardia, hypotension, hypothermia, alveolar hypoventilation, obstipation, or ileus, and sometimes water intoxication or hypoglycemia.²²⁴ Patients are often elderly. The condition if untreated progresses to fatal hypotension.

In the cases of myxedema coma arising spontaneously in the community, stupor progresses over several days, and families report that the number of hours spent sleeping has gradually increased to include most of a 24-hour period. Seizures have been reported.²²¹ In history taking it is important to ask whether the patient with suspected myxedema coma formerly was diagnosed with hypothyroidism or formerly was treated with radioactive iodine or surgery for overactive thyroid. On physical examination overt manifestations of myxedema are apparent. The patient often can be aroused and will make monosyllabic responses to questioning before lapsing back into stupor. Breathing is stertorous. Some patients with an infectious process may not have a fever. The most ominous sign of impending myxedema coma for a hypothyroid patient under inpatient observation is progressive hypothermia.

In contrast to patients with nonthyroidal illness syndrome, the laboratory evaluation will demonstrate low free T₄ and high TSH in the majority of true cases of myxedema coma. Myxedema coma resulting from pituitary failure is uncommon.²²⁷

APPROACH TO MANAGEMENT

Before initiating therapy for myxedema coma, the caregiver should question whether the hypothyroid patient is experiencing a self-limited consequence of a definable precipitating event. Stupor may be induced by sedatives and analgesics, especially opiates, and may resolve without rapid thyroid hormone replacement. Hyponatremia may be induced by intravenous fluid therapy. Short-term ventilator dependency may result from surgery. Yet each of these complications by itself does not require rapid replacement of thyroid hormone therapy unless conservative management fails.

A blood sample should be withdrawn for determination of TSH, free T₄, and serum cortisol levels before treatment is initiated. In the presence of progressive hypothermia and with a clinical picture of advanced myxedema, therapy should be initiated before the return of the results of thyroid function tests. If the TSH level is not elevated, the diagnosis of myxedema coma must be questioned. The needed initial dose of levothyroxine is unlikely to cause adverse effects, should the laboratory studies unexpectedly suggest euthyroidism or nonthyroidal illness syndrome.

The patient should be treated in an intensive care unit. Complications during treatment of myxedema coma include gastrointestinal bleeding and intracranial hemorrhage, which may result from coagulopathy resulting from myxedema itself. Pressors are generally ineffective in combating hypotension and may precipitate arrhythmia. Efforts at rewarming the patient may precipitate shock as a result of vasodilation in an individual whose cardiac output cannot match the demand. Treatment should include fluid restriction, avoidance of hypotonic fluids, administration of glucose as concentrated solutions if required, avoidance of pressors, and use of ordinary blankets for rewarming. Respiration should be supported as needed to treat alveolar hypoventilation.

The author would advise restricting use of a 400- to 500-µg levothyroxine intravenous bolus to those patients whose myxedema coma arose in the community without obvious precipitating cause and who are known to have normal serum albumin and absence of cardiac risk factors. If the

patient is hypoalbuminemic or the serum albumin is unknown, or if the patient has cardiac risk factors, an initial 200- to 300- μ g levothyroxine intravenous bolus should be used for myxedema coma, and, if coexistent precipitating illness is present, combination therapy with liothyronine (triiodothyronine, T_3) could be considered. If an albumin level is subsequently reported normal and if the patient demonstrates no arrhythmia or manifestations of cardiac ischemia, 100 μ g of levothyroxine can be added every several hours to bring the cumulative dose up to 500 μ g in the first 24 hours. Such replacement provides protection against relapsing hormonal deficiency in a way that short-acting T_3 monotherapy cannot. The oral route is unsatisfactory for initial therapy because of the likelihood of ileus or delayed absorption. After intravenous treatment, T_4 can be withheld for several days until the patient is able to take medication orally, or 50 μ g of levothyroxine daily can be administered intravenously beginning on the second day. Hydrocortisone 100 mg every 8 hours is given during the first 24 hours. Glucocorticoids are tapered and discontinued before discharge. There should be a low threshold for evaluation for the presence of coronary artery disease.

THERAPEUTIC ALTERNATIVES

There is not sufficient evidence to strongly advocate for or against therapy with liothyronine (triiodothyronine, T_3). Arguments in favor of intravenous levothyroxine as monotherapy include its long history of successful use, its ability to prevent relapsing of hypothyroidism, avoidance of supranormal levels of T_3 , and the observation that in the absence of intercurrent illness T_3 levels become normal within 24 hours.

Theoretical controversy continues to exist on whether to include intravenous liothyronine in the initial treatment plan. Some authorities recommend using both hormones at the outset, especially if coexistent illnesses are present that might impede conversion of T_4 to T_3 .^{227,234} Additional arguments in favor of including liothyronine relate to the delayed conversion of T_4 that is seen in hypometabolic patients and the more rapid effect on tissues when T_3 therapy is used.¹⁸¹ In combination therapy, the recommended intravenous doses are approximately 10 μ g of liothyronine initially and 10 μ g of liothyronine every 8 to 12 hours on the first day, combined with an initial loading dose of about 200 to 250 μ g levothyroxine. This treatment is followed by approximately 100 μ g of levothyroxine daily intravenously on the second day and 50 μ g levothyroxine daily thereafter. On the other hand, it has been speculated that some cases of fatality were caused by relatively high T_3 levels attained early in therapy.²²⁵ Conventional treatment with levothyroxine alone has not been shown to be inferior and is generally effective.

PROGNOSIS

Patient findings associated with fatality have included old age, cerebrovascular bleeding, or myocardial infarction during treatment^{213,225,226,229} or suspected coronary events after recovery.²¹⁸ In a series of 11 cases the level of consciousness, Glasgow score, and APACHE II score were predictive of death.²³² Treatment factors associated with fatality may include overly gradual oral regimen of replacement of thyroid hormone, high replacement doses of thyroid

hormone [liothyronine (triiodothyronine, T_3) doses = 75 μ g/day, levothyroxine doses = 500 μ g/day], or high measured levels of T_3 during treatment.^{213,225,229} Within 6 to 36 hours most patients treated with T_4 in sufficient dosage experience a rise of temperature and blood pressure; improvement of mentation; and through peripheral conversion of T_4 , correction of low T_3 levels.

HYPERTHYROIDISM, THYROID STORM, THYROCARDIAC CRISIS, AND CORONARY ARTERY SPASM

HYPERTHYROIDISM

In the United States, with reference to the uptake of radioactive iodine during diagnostic testing, the common causes of high-uptake hyperthyroidism are Graves' disease, toxic multinodular goiter, and toxic adenoma. Low-uptake causes of endogenous hyperthyroidism are recognized, having a self-limited course, and medications may cause hyperthyroidism.

PREVALENCE AND INCIDENCE

The age-related incidence of hyperthyroidism depends on the cause of hyperthyroidism.^{141-143,235,236} The prevalence of overt hyperthyroidism is between 0.5% and 2% in women, and is 10 times more common in women than in men in iodine replete areas, with an annual incidence rate of 0.4 per 1000 women and 0.1 per 1000 men.^{141,143} In Sweden the overall incidences of Graves' disease, toxic multinodular goiter, and toxic adenoma were 17.7, 5.4, and 2.7 per 100,000 persons per year, respectively, but the peak age-specific incidence of toxic multinodular goiter and toxic adenoma occurred in the 80-plus age group: 31.5 per 100,000 persons per year.²³⁵ In the ambulatory setting among adult patients, the overall prevalence of subclinical hyperthyroidism (isolated TSH suppression) is 0.5% to 6.3%, with variability dependent on population under study, inclusion or exclusion of patients with thyroid disease, and definition of threshold TSH for inclusion.¹⁴¹⁻¹⁴³

PATHOGENESIS

In the hyperthyroidism of Graves' disease, the TSH receptor/G protein/adenylyl cyclase complex is activated by abnormal thyroid-stimulating immunoglobulins with affinity for the TSH receptor. The associated phenomena of orbitopathy and dermopathy also are thought to result from autoimmune processes. In some cases of hyperthyroidism resulting from toxic adenoma, a G protein mutation is demonstrable that results in activation of the membrane adenylyl cyclase associated with the TSH receptor complex. Plummer's disease (toxic multinodular goiter) is most commonly seen in older patients and represents a late outcome in the natural history of euthyroid multinodular goiter. Because of TSH suppression, in toxic multinodular goiter the internodular thyroidal tissue is metabolically inactive in accumulating iodine.

In susceptible individuals, especially those from iodine-deficient regions of the world or with preexisting nodular thyroid disease, hyperthyroidism can be produced by iodine (Jod-Basedow phenomenon). Hyperthyroidism can

be produced by glandular destruction, as in thyroiditis, characterized by having low radioactive iodine uptake. Common causes of low-uptake hyperthyroidism include silent thyroiditis, postpartum thyroiditis, subacute thyroiditis, and exogenous thyroid hormone. Substances implicated in drug-induced forms of destructive thyroiditis causing hyperthyroidism include amiodarone, lithium, interferon- α , interleukin 2, iodine, and iodinated contrast agents.²³⁶ Two different mechanisms of hyperthyroidism are possible during amiodarone therapy: iodine-induced thyrotoxicosis and drug-induced thyroiditis.

In general, intense activation of the TSH receptor complex results in an increased ratio of T_3 to T_4 resulting from direct thyroidal T_3 secretion. The augmentation of thyroidal T_3 release of hyperthyroid patients may result in part from enhancement of the thyroidal type 2 deiodinase activity.²³⁷ The altered ratio of T_3 to T_4 is not observed in destructive hyperthyroidism.²³⁸

Hyperthyroidism is characterized by hypermetabolism and increased thermogenesis. There is enhanced target organ response to sympathoadrenal stimuli. Multisystemic changes of organ physiology occur. Of special interest to the intensivist is the pathophysiology of the cardiac manifestations, discussed in the section on “Thyrocardiac Crisis and Coronary Spasm.”

CLINICAL MANIFESTATIONS

Intubation and central lines may prevent adequate palpation of the thyroid. If thyroidal bruit is detected on auscultation of the upper poles of the lateral lobes of the thyroid in a hyperthyroid patient, the classification of the cause of hyperthyroidism as Graves' disease essentially is assured. The eyes, nails, and skin should be examined for evidence of orbitopathy, onycholysis, fine skin quality (smooth elbows), or dermopathy (“pretibial myxedema”). The remainder of the physical examination is likely to yield findings that are suggestive of hyperthyroidism but nonspecific, such as hyperhidrosis, atrial arrhythmia, hyperdynamic heart, precordial lift, systolic ejection murmur, S_3 gallop, restlessness, hyperkinesia, agitation, or briskness of Achilles reflexes. In severe cases, adrenal reserve may be insufficient.²³⁹ A different spectrum of symptoms and signs has been reported in the elderly, who may appear apathetic or depressed, and among whom the average number of thyrotoxic symptoms may be as low as two, with dominance of weight loss, proximal myopathy, tremor, and cardiac manifestations such as heart failure, sinus tachycardia, or atrial fibrillation.²⁴⁰⁻²⁴³

DIAGNOSTIC APPROACH

Laboratory Diagnosis

The laboratory findings will include TSH below 0.1 μ IU/mL and usually elevation of total and free T_4 . If the T_4 level is normal and TSH is below 0.1 μ IU/mL, elevated T_3 will identify T_3 toxicosis. Diagnosis of amiodarone-induced thyrotoxicosis requires demonstration of low TSH, and a T_3 level higher than the low levels typical of the euthyroid amiodarone-treated patient.

T_4 Hyperthyroidism

The finding of high T_4 without high T_3 , although atypical of hyperthyroidism, sometimes occurs after surgery, during

exposure to substances that block conversion of T_4 to T_3 , among the elderly or the critically ill, or sporadically. During the acute illness, differentiation between euthyroid hyperthyroxinemia and hyperthyroidism may be difficult.²⁴⁴⁻²⁴⁸

Subclinical Hyperthyroidism

Stable TSH suppression outside the critical care setting, sustained over several months, in the absence of drug effects or pituitary or hypothalamic disease, and without concomitant iodothyronine elevations, suggests subclinical hyperthyroidism. Patients with toxic nodular goiters in the early years of their disease may have TSH suppressions that are only marginal, and yet the diagnosis of subclinical hyperthyroidism can be suspected by thyroid palpation and confirmed by finding autonomous nodularity on thyroid scanning.

Determining the Cause

Classification of hyperthyroidism according to radioiodine uptake provides information about the expected course of the thyrotoxicosis and appropriateness of treatment alternatives. The so-called high-uptake forms of hyperthyroidism (Graves' disease, toxic adenoma, toxic multinodular goiter, and TSH-secreting pituitary adenoma) are appropriately treated with thionamide drugs. The low-uptake forms caused by destructive thyroiditis or iodine are treated primarily by beta blockers and possibly corticosteroids, depending upon cause and severity, and are self-limited in duration. In high-uptake forms of hyperthyroidism, a 24-hour radioiodine uptake evaluation sometimes yields intermediate range or normal results, suggesting mild disease or an unrecognized source of exogenous iodide. In toxic adenoma and toxic multinodular goiter, even though these disorders are classified as high-uptake forms of hyperthyroidism, a normal or high normal uptake is common (see discussion under “Diagnostic Approach to Thyroid Disease”). In the critical care setting, radioiodine uptake and scanning tests may be impracticable. Ultrasonography may define the vascularity of the gland and the presence or absence of nodularity. A thyroidal bruit, endocrine orbitopathy, or high levels of antibodies to the TSH receptor may suggest that Graves' disease is the probable cause of hyperthyroidism.

APPROACH TO MANAGEMENT

If endogenous hyperthyroidism was recognized before hospitalization, and if biochemical euthyroidism had been maintained until the time of admission by use of a stable dosage of antithyroid medication, the established dose probably should be maintained during the critical illness.

For those having subclinical hyperthyroidism, the 2011 Hyperthyroidism Management Guidelines of the American Thyroid Association and the American Association of Clinical Endocrinologists suggest that persistent findings of TSH at 0.1 μ IU/mL or below over 3 to 6 months should lead to determination of cause, with a decision for treatment or observation determined by patient characteristics.^{162,164,236}

For those critically ill patients having overt hyperthyroidism classifiable as a probable high-uptake form, generally treatment should consist of antithyroid medication (Fig. 60.5). Management of most aspects of overt hyperthyroidism are addressed in the guideline, including many of the issues important to critical care medicine.²³⁶ The drugs used in treatment of hyperthyroidism include the

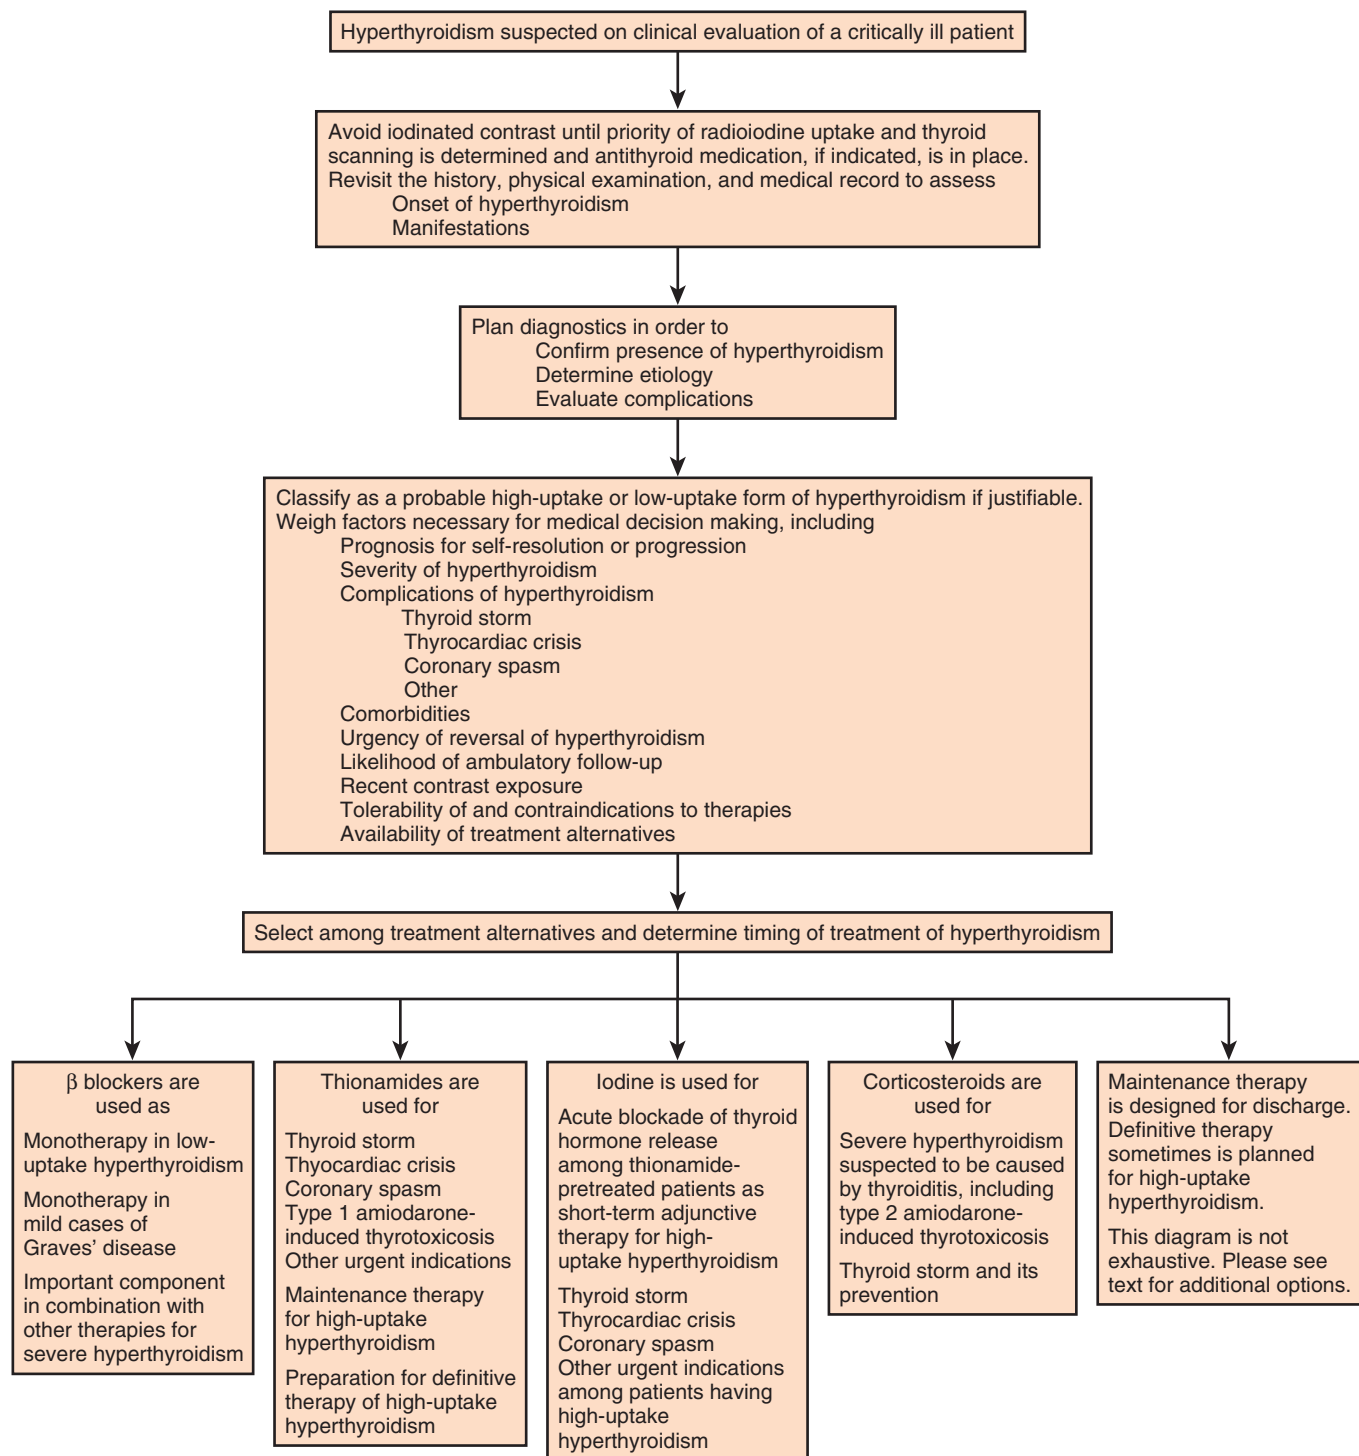

Figure 60.5 Approach to management for hyperthyroidism.

thionamides propylthiouracil and the longer-acting drug methimazole.²⁴⁹⁻²⁵⁹ Thionamides inhibit the coupling of moieties on TG and organification of iodide, thus preventing storage and synthesis of thyroid hormone. By inhibiting 5'-monodeiodination of T_4 by the D1 enzyme, propylthiouracil reduces peripheral conversion of T_4 to T_3 .^{249,260} To initiate therapy it is common practice to start with a

relatively higher dose than will be required for maintenance and to choose a dosage on the basis of the apparent clinical severity of hyperthyroidism and size of the thyroid gland. Methimazole can cause a reversible cholestatic picture of hepatic injury. Propylthiouracil, however, can cause irreversible hepatic necrosis resulting in fatality.²⁵⁶ Both drugs can cause neutropenia or agranulocytosis.²⁶¹ A rare adverse

effect of propylthiouracil is antineutrophil cytoplasmic antibody-positive vasculitis. Methimazole taken in the first trimester of pregnancy has been associated with aplasia cutis and choanal atresia of the neonate. When thionamide drug therapy is chosen, except for hyperthyroidism during the first trimester of pregnancy, for thyroid storm, or for patients having a history of a minor reaction to methimazole, because of the difference in severity of potential hepatotoxicity, the preferred drug for virtually every patient is methimazole rather than propylthiouracil.²³⁶ For uncomplicated hyperthyroidism the initial daily dosage might be propylthiouracil 50 to 150 mg every 8 hours or methimazole 10 mg twice daily. After control is achieved, methimazole usually is converted to once-daily therapy and, after gradual dose reduction, sometimes is given in doses as little as 5 mg daily. Once control is achieved, methimazole may be given as a single daily dose. Propylthiouracil may be reduced to as little as 50 mg two or three times daily but must be administered in a divided dosage to prevent escape.

During hyperthyroidism beta-blocker therapy is the preferred method of controlling tachycardia and peripheral manifestations of sensitivity to catecholamines. Among the beta blockers, there is the greatest experience with propranolol. The metabolism of propranolol is enhanced, and blood levels are highly variable in hyperthyroidism. Most patients requiring enteral propranolol for hyperthyroidism should begin with 10 to 40 mg every 6 hours. Other beta blockers have been used, and some advocate cardioselective agents.²⁶²⁻²⁷⁸ Definitive treatment of hyperthyroidism consists of radioactive iodine or surgery. Use of radioiodine therapy is inappropriate for low-uptake hyperthyroidism.

Conservative management of low-uptake causes of hyperthyroidism consists of observation or beta blockers. In cases of amiodarone-induced thyrotoxicosis, in order to define a treatment strategy that might include corticosteroids, an effort should be made to classify the hyperthyroidism as type 1 or type 2 amiodarone-induced thyrotoxicosis.

Classification and Management of Amiodarone-Induced Thyrotoxicosis

Hyperthyroidism may occur in up to 6% of amiodarone-treated patients in iodine-sufficient regions, and in up to 9.6% or more of treated patients in iodine-deficient regions.^{30,236} A regimen recommended for detection of thyroid dysfunction during amiodarone therapy is to check before and at 1 and 3 months following initiation, and then at 3- to 6-month intervals thereafter.²³⁶ Amiodarone-induced thyrotoxicosis may be recognized by characteristic clinical and laboratory findings, including tachycardia, weight loss, proximal muscle weakness, low TSH, and high or high normal T₃ and free T₃.²⁷⁹⁻²⁹² Classification as type 1 or type 2 amiodarone-induced thyrotoxicosis is based on the mechanism of the hyperthyroidism. Type 1 amiodarone-induced thyrotoxicosis is a Jod-Basedow type of hyperthyroidism consequent to the high iodine content of amiodarone, likely to be associated with preexisting nodular goiter or, less commonly, Graves' disease. On color flow Doppler examination, the gland may appear hypervascular. Despite the iodine exposure from amiodarone, the radioiodine uptake, though relatively low, may be measurable, and technetium MIBI (methoxyisobutylisonitrile) scanning may show areas of uptake. Type 2 amiodarone-induced thyrotoxicosis, now by

far the more common type, results from a drug-related destructive thyroiditis, often occurring in a patient having no prior history of known thyroid disease and not having thyroidal enlargement, sometimes recognized by markedly diminished vascularity on color flow Doppler examination.^{284,289} Radioiodine uptake is negligible or absent. When the differentiation can be made, type 1 and type 2 amiodarone-induced thyrotoxicosis are addressed by different management strategies.²⁹¹ In type 1 amiodarone-induced thyrotoxicosis, thionamide therapy is used. Because there is unlikely to be a full response during continuation of amiodarone, the usual recommendation is to interrupt amiodarone for type 1 amiodarone-induced thyrotoxicosis. Once the iodine stores from the previous treatment have dissipated, radioactive iodine may be administered to ablate the thyroid in preparation for reinstitution of amiodarone, especially if hyperthyroidism still is demonstrable. Sometimes surgery is the best option available for the treatment of resistant cases of type 1 amiodarone-induced thyrotoxicosis.²⁷⁹ Postoperatively amiodarone may be reinstituted.

For type 2 amiodarone-induced hyperthyroidism, the course of the hyperthyroidism may be transitory, with subsequent development of hypothyroidism among some patients.^{31,32} Glucocorticoids promote resolution of type 2 amiodarone-induced thyrotoxicosis.^{280,290} During glucocorticoid therapy it is not necessary to interrupt amiodarone.^{288,292} A typical starting dose is 30 mg prednisone daily.²⁹² Because there may be mixed types or indeterminate presentations in which the classification of the amiodarone-induced thyrotoxicosis may be uncertain, in actual practice thionamides and glucocorticoids both may be used during initiation of treatment. In this country, perchlorate, another option, is not available.

Precautions in the Care of the Hyperthyroid Patient

Thyrotoxic patients display enhanced susceptibility to sympathetic stimuli and adrenergic drugs. They may be volume depleted and may not tolerate excessive diuresis. Before administering contrast material, the physician should consider whether the radioactive iodine uptake or thyroid scanning tests can be deferred. Administration of a thionamide should precede use of iodinated substances.

Preparation of the Thyrotoxic Patient for Emergency Nonthyroidal Surgery

Elective surgery should be deferred until euthyroidism is attained. In deciding whether to operate, the risk of perioperative fatality due to hyperthyroidism has to be weighed against the strength of the medical indications for immediate surgery. Before emergency surgery, the risk of thyroid storm obligates the caregiver to prepare the patient with antithyroid treatment.²⁹³⁻²⁹⁵ For newly diagnosed patients with endogenous hyperthyroidism requiring rapid preparation for emergency surgery, preoperatively propylthiouracil 200 mg every 4 hours or methimazole 20 mg every 4 hours has been recommended.²⁹⁴ At least 2 hours after the first dose of propylthiouracil, the patient should receive iodide. Iodate or iopanoic acid (as described later in the section on treatment of thyroid storm) are potentially useful but unavailable in many countries. In the absence of contraindications, propranolol orally in a dosage up to 20 to 40 mg

four times per day or more should be started. The regimen should be continued in the immediate postoperative period by use of a nasogastric tube if necessary. By the time of discharge methimazole would be the preferred thionamide, and the dose should be tapered. Glucocorticoids also may have a role in preoperative preparation, initially 100 mg hydrocortisone every 8 hours.

ALTERNATIVES FOR TREATMENT

For patients who cannot take oral medications, antithyroid drugs can be prepared for rectal administration.^{251,252} Patients with a history of minor skin reactions to one thionamide may be treated with the other. Patients with a history of hepatocellular jaundice during propylthiouracil therapy may be treated with methimazole.^{254,257} Lithium has been used for the control of hyperthyroidism in patients unable to use propylthiouracil or methimazole, starting at a dose of 300 mg twice per day.^{254,296-299} The ability of the radiographic contrast agents iopanoic acid and ipodate to inhibit thyroid hormone release, peripheral conversion of T_4 , and possibly nuclear binding of T_3 has been exploited in certain hyperthyroid states including cases of destructive hyperthyroidism and in thionamide intolerance.³⁰⁰⁻³⁰⁵ The use of radiographic contrast agents usually should be adjunctive to thionamides and beta-blocker therapy. Instances of escape after prolonged use of iodinated substances have been reported.³⁰² Therefore, if a radiographic contrast agent is used as an antithyroid medication without antecedent and concomitant thionamide medication, some patients will require thyroidectomy as soon as reasonable control has been obtained.²⁹⁵ Recommended daily doses are ipodate 500 to 1000 mg orally or iopanoic acid 500 mg twice daily. These iodinated oral cholecystographic agents have not been clinically available in the United States recently.

For patients with contraindications to the use of beta blockers, older regimens included guanethidine³⁰⁶ or reserpine,³⁰⁷ which are seldom used at present. For control of heart rate in patients with reversible airway disease, diltiazem is an alternative to beta blockers.^{308,309} Iodine has been used to reduce vascularity of the thyroid and inhibit thyroid function. Brief treatment with iodine may hasten clinical recovery by acutely blocking release of thyroid hormone (see section "Thyroid Storm and Thyrocardiac Crisis"). Thionamide administration must precede use of iodine, and must be continued during treatment. Accidental gastrointestinal injuries have been reported.³¹⁰⁻³¹²

PROGNOSIS

After a treatment course with thionamides administered for as long as 18 to 24 months, a variably reported percentage of patients with Graves' disease (probably <50%) will be in remission. Some will develop hypothyroidism as a result of Hashimoto's disease. With toxic adenoma, remission of hyperthyroidism is uncommon. With toxic multinodular goiter, hyperthyroidism is persistent. Low-uptake forms of hyperthyroidism are self-limited conditions, and hyperthyroidism usually resolves within 6 months. If there is an offending drug, the mechanism of hyperthyroidism and the importance of the drug to patient well-being have to be weighed in deciding whether discontinuation should be advised. Storage of amiodarone in adipose tissue may prolong the episode of thyroid dysfunction. The

hyperthyroidism of destructive thyroiditis, as may be seen with lithium therapy or type 2 amiodarone-induced hyperthyroidism, may self-resolve with the passage of time, or the thyrotoxicosis may be followed by a more prolonged period of hypothyroidism.

Socioeconomic factors coupled with a lapse in care may account for some of the long-term morbidity and mortality risks associated with hyperthyroidism.³¹³ Some cardiovascular abnormalities may persist after treatment of hyperthyroidism. Some but not all epidemiologic studies suggest that an increased overall mortality risk is associated with a history of hyperthyroidism, even after radioiodine treatment.³¹⁴⁻³²²

THYROID STORM

Thyroid storm is a potentially lethal complication of hyperthyroidism, managed in the critical care setting.^{231,236,323-327} In a hyperthyroid patient the diagnosis of this emergency is based on the clinical presentation.*

HISTORY AND INCIDENCE

In the present day, thyroid storm is seen after the development of intercurrent illness or infection, operative intervention for nonthyroidal illness, or infrequently after exposure to medications that exacerbate either the severity of hyperthyroidism or patient sensitivity to thyroid hormone excess. Initially this entity was recognized as a complication of thyroidectomy for hyperthyroidism that had been performed in unprepared patients.³²⁸ In an early series, two thirds of the patients died³²⁹; postmortem examinations were not illuminating. After it was recognized that patients should be rendered euthyroid before thyroidectomy, the incidence of storm after thyroidectomy declined, and the literature began to focus on nonsurgical precipitating factors.^{331,332} As early as 1960, after the use of reserpine and glucocorticoids was added to therapy with antithyroid medication and iodide, it was reported that the mortality rate from thyroid storm had been reduced from 60% or 70% nearly to 25%.³³² In 1966 the importance of initiating thionamide therapy before iodide administration was emphasized.³³⁴ By employing guanethidine as reported in 1969³⁰⁶ or reserpine therapy reported in 1970,³⁰⁷ the mortality rate of thyroid storm in small series was as low as 7% and 0%, respectively. By the mid-1970s the use of propranolol had largely replaced earlier methods of attaining sympathetic blockade.^{262,264,266,337}

Thyroid storm is a relatively infrequent reason for admission to critical care units. Even before the existence of modern antithyroid therapy, the estimated incidence of thyroid storm among patients hospitalized for hyperthyroidism was only 7%.³³²

PATHOGENESIS

Graves' hyperthyroidism is the most common thyroid disorder identified with thyroid storm, but storm has also been associated with toxic multinodular goiter, amiodarone-induced hyperthyroidism,²⁸² and rarely exogenous thyroid hormone overdosage.^{330,345,347,363} Precipitating factors precede the development of thyroid storm in the

*See References 239, 247, 262, 278, 297, 306, 307, 328-375.

majority of cases. Identifiable events accompanying thyroid storm may include infection,³³⁵ surgery,^{328,329,335,372} administration of radioactive iodine,^{331,341,357} recent exposure to iodine or iodinated contrast dye, or withdrawal of inorganic iodide,^{329,354} trauma,^{48,361,368} parturition,³³³ diabetic ketoacidosis,^{358,366} status epilepticus and stroke,³⁵¹ pulmonary embolism,³³² pseudoephedrine administration,³⁴⁶ other precipitating events, discontinuation of antithyroid medication,³³¹ or a lapse in care.³⁴⁰ In the absence of thionamide therapy, administration of iodine-containing compounds floods the gland with iodine, but inhibition of hormone release by iodine may be incomplete or temporary, and thyroid storm may occur during continued administration of iodine.³²⁹ Recently instituted or incompletely effective thionamide therapy does not necessarily protect against storm induced by radiation thyroiditis.³⁴⁴ Reliance on lithium²⁹⁷ or propranolol²⁶⁵ as monotherapy for preoperative preparation may be responsible for thyroid storm.

In thyroid storm the T_3 and total T_4 levels are not different from levels in uncomplicated cases of hyperthyroidism, but the dialyzable fraction of T_4 (the percentage that is free) is higher.^{338,339} This finding has been taken to support the idea that the medical illness may cause acute unbinding of thyroid hormone from transport proteins. Relative adrenal insufficiency may be present.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The definition of thyroid storm has come to include a constellation of fever greater than 100° F, tachycardia out of proportion to fever, and exaggerated manifestations of thyrotoxicosis affecting at least two other of the following systems: cardiac, gastrointestinal, or neurologic.³³² A clinical scoring system for identifying thyroid storm has been endorsed in which identification of a precipitating factor is one diagnostic criterion.^{236,324} The system also identifies a range of scores that is used to classify a patient's presentation as impending thyroid storm. Cardiac findings may include marked tachycardia out of proportion to fever, atrial arrhythmia, heart failure, shock, ventricular tachycardia, and ventricular fibrillation.^{352,364,369,371} Gastrointestinal symptoms include hyperdefecation, diarrhea, vomiting, abdominal pain, acute abdomen,^{349,350,370} and jaundice or liver failure.^{353,355,356,375} Hepatic failure usually is a result of right-sided heart failure. Rhabdomyolysis may occur.³⁴² Neurologic features include tremulousness, agitation, hyperkinesia, muscle weakness, delirium or psychosis, apathy, prostration, seizures, or obtundation. Brisk contraction and relaxation time often are observed when deep tendon reflexes are elicited. Fever is the hallmark of the condition, sometimes as high as 106° F. As a practical matter, even if another underlying cause of fever is identified, any febrile patient (temperature >100° F) who has known hyperthyroidism with marked tachycardia or exaggerated manifestations of hyperthyroidism is best treated as having impending thyroid storm.

No specific laboratory finding defines the presence of thyroid storm, but rather, thyroid storm is defined by the characteristic clinical picture, which will be accompanied by laboratory findings of TSH suppression and generally free T_4 elevation. Measurement of T_3 is not necessary unless free T_4 levels are normal.³³⁶ Rarely, in the presence of coexisting illness, the T_4 may be elevated but total T_3 may be normal.²⁴⁷

APPROACH TO MANAGEMENT

Although thionamides block the synthesis of thyroid hormone, this effect will not benefit the patient until several weeks later, when thyroid glandular stores of preformed hormone have been discharged. To block hormone release acutely, iodide is administered. Thionamide pretreatment with a loading dose is essential to induce a biosynthetic blockade that will prevent flooding of the gland with iodide, with the attendant future risk of exacerbation of hyperthyroidism. Glucocorticoid therapy is employed to correct potential relative adrenal insufficiency.²³⁹ Beta blockers combat cardiac sensitivity to catecholamines and reduce central and peripheral neurologic manifestations of hyperthyroidism. Propylthiouracil, glucocorticoids, and propranolol block conversion of T_4 to T_3 .

Treatment of thyroid storm requires thionamide, beta blocker, and glucocorticoid doses higher than usually required for ordinary care. There is no comparative evidence that would support specific titration rules or a preference among differing dose ranges that have been recommended for thionamides and beta blockers.^{231,236,323-326,337} Nevertheless, although incomplete response to beta blockers could require upward dose titration, caution should be exercised in the initial dosing, and tolerance to the initial dose should be demonstrated.

A reasonable starting regimen is an initial propylthiouracil loading dose of 600 mg, and thereafter a continued dose of 200 mg every 4 hours, or 1200 mg daily in divided dosage, given orally or by nasogastric tube. The literature suggests that the initial propylthiouracil loading dose may be as high as 1000 mg, with a continued dose of 250 mg every 4 hours, or 1500 mg daily. Propylthiouracil inhibits peripheral conversion of T_4 to T_3 and therefore is favored over methimazole in thyroid storm. Alternatively, methimazole 60 to 80 mg per day in divided dosage may be used.^{324,325,337} These doses are reduced as the patient begins to respond. Beginning 1 to 2 hours after the loading dose of propylthiouracil or methimazole, saturated solution of potassium iodide, 5 drops every 6 hours, is given, or Lugol's solution, 30 drops daily in divided dosage three to four times a day. Hydrocortisone is administered in a dose of 100 mg every 8 hours. Beta-blocker therapy is considered to be one of the mainstays of therapy, useful for control of tachyarrhythmias and other manifestations of the characteristic increased sensitivity to catecholamines. Although the literature on beta-blocker therapy during thyroid storm acknowledges use of or requirement for extremely high doses in some cases, nevertheless adverse effects including hypotension or cardiorespiratory arrest also may be seen in conjunction with beta-blocker therapy.^{277,278} For patients having evidence of heart failure or hypotension or developing these findings during treatment, beta blockers must be given during hemodynamic monitoring with great caution, and alternative methods of controlling heart rate and rhythm should be considered. Despite evidence that extremely high doses may be required by some patients, a starting oral dose of propranolol as low as 20 to 40 mg every 6 hours has been recommended.³²⁵ The propranolol dose requirement may be as high 480 mg daily, given as 60 to 80 mg propranolol every 4 hours, or 80 to 120 mg every 6 hours.^{231,323,326} With monitoring of blood pressure and rhythm, while awaiting the effects of orally administered propranolol, 0.5 to 1 mg

propranolol intravenously may be cautiously provided; the dose may be increased to 2 to 3 mg over 15 minutes if tolerated.³²⁴ Digoxin is used for atrial fibrillation. The underlying cause of thyroid storm must be identified and treated, cultures made, and in general empiric antibiotics may be considered until infection is excluded. Because salicylates may promote unbinding of thyroid hormone from transport proteins, for control of fever, acetaminophen is preferred, and cooling blankets may be required. Hemodynamic monitoring should be provided as appropriate. Fluid and electrolyte replacement are necessary, and administration of vitamins is prudent.

Often, propylthiouracil is tapered by the time of discharge to 300 to 600 mg daily in divided dosage, or methimazole to a dose of 30 to 60 mg, with intent for further outpatient dose reduction. The glucocorticoids are tapered and discontinued, and the iodide dose is reduced to 2 drops three times per day. The iodide therapy is discontinued within 2 weeks. In consideration of the desirability of future radioactive iodine therapy, it is important to anticipate potential financial, philosophic, or emotional barriers to follow-up care and definitive therapy.

THERAPEUTIC ALTERNATIVES

For thyroid storm propylthiouracil normally is administered enterally, but the rectal route for administration has been described.^{253,259} Lithium is not a substitute for thionamide therapy unless unacceptable intolerance to thionamide therapy has been demonstrated. The initial dose of lithium in this setting is 300 mg every 6 hours.³²⁵ The route of administration of iodide may be sublingual or rectal by retention enemas.^{253,350} Iodate therapy 500 mg once or twice daily and iopanoic acid are effective, but these agents presently have become unavailable in many countries.³⁰⁵ For patients at risk of cardiac decompensation, the rapid-acting drug esmolol may replace propranolol as initial intravenous therapy, used while awaiting the effects of orally administered cautious doses of propranolol.²⁷⁵ Adjuncts to therapy, reserved for resistant cases, include peritoneal dialysis, plasma exchange, or plasmapheresis.* Thyroidectomy also has been used successfully for iodine-induced storm and failure of medical management.^{354,359,362}

PROGNOSIS

Clinical markers suggesting a poor prognosis include delay in therapy, coma, jaundice, and shock. Normalization of temperature, drop of heart rate, and improved mental status are favorable signs. With treatment as described earlier, a sharp reduction of circulating thyroid hormone concentration is observable by the second hospital day, but it may be several days before adequate stabilization of clinical manifestations is seen.³²⁵

THYROCARDIAC CRISIS AND CORONARY ARTERY SPASM

In most cases of overt hyperthyroidism and in thyroid storm, cardiac manifestations are one component of a multisystem presentation. Chest discomfort is not an uncommon

complaint among patients with hyperthyroidism, even among the young, and usually has benign significance. Characteristic anginal symptoms are uncommon. Sometimes, however, cardiac manifestations dominate the clinical presentation, especially in the elderly or in patients whose cardiac events emerge suddenly.* Whereas the full evolution of most manifestations of hyperthyroidism emerge over an extended period, the sudden onset of thyrocardiac effects may complicate any form of thyrotoxicosis, even fleeting or recent-onset thyrotoxicosis, such as that resulting from subacute thyroiditis or overdosage of thyroid hormone, and may occur among young patients. In the absence of other criteria permitting a diagnosis of thyroid storm, thyrocardiac symptoms may present with a medical crisis.

PREVALENCE AND INCIDENCE OF THYROCARDIAC DISEASE

Thyrocardiac crises without storm are relatively more common than thyroid storm.³⁷⁶⁻³⁷⁹ Preexisting heart disease and age older than 60 are risk factors for manifestations of thyrocardiac disease.^{377,379,380} Among 462 patients with hyperthyroidism who had no associated organic heart disease and who were referred for radioactive iodine, a 1958 study reported the prevalence to be atrial fibrillation 10%, congestive heart failure with atrial fibrillation 5%, and congestive heart failure with sinus rhythm 0.6%.³⁷⁷ In a study of unselected hyperthyroid patients, the prevalence was atrial fibrillation 9% and congestive heart failure 6%.³⁷⁹ In the Framingham Heart Study, for persons with TSH levels 0.1 μ IU/mL or less compared with persons with normal TSH, the relative risk of atrial fibrillation was 3.1 (95% confidence interval, 1.7 to 5.5). Among patients with TSH suppression of less severity (i.e., >0.1 μ IU/mL), the risk for atrial fibrillation was comparable with the risk among people with normal TSH.³⁸¹ After emergency presentation with atrial fibrillation, screening for hyperthyroidism may be justified by the possibility of detecting unrecognized cases of hyperthyroidism.^{382,385} No body of literature exists on predictors of myocardial infarction, ventricular arrhythmia, or sudden death. The occurrence of coronary ischemic events during hyperthyroidism had been considered to be surprisingly low. In an early series of unselected hyperthyroid patients, 2 of 200 died as a result of myocardial infarction.³⁷⁹ In one study, high levels of T_3 on admission were associated with the presence of a coronary event and also predicted subsequent coronary events over a 3-year follow-up period.¹²⁶ Isolated case reports document the occurrence of sudden death or coronary spasm even among young patients.

PATHOPHYSIOLOGY

Structural and regulatory proteins in the heart are encoded by genes regulated by T_3 .¹¹⁵ Despite the low levels of circulating catecholamines, the physiology of a hyperthyroid patient resembles a hyperadrenergic state.³⁸⁶ Sinus tachycardia is the most common arrhythmia in uncomplicated hyperthyroidism. On examination there are characteristically tachycardia at rest, widened pulse pressure, and systolic hypertension. The patient with hyperthyroid heart disease has a high left ventricular ejection fraction at rest, high

*See References 343, 344, 365, 367, 373, 374.

*See References 115, 119, 120, 126, 376-385.

cardiac output, subnormal response to exercise, and sometimes rate-related heart failure.³⁷⁶ Physiologic abnormalities include decreased systemic vascular resistance; increased blood volume; increased work load; increased contractility; shortening of systolic contraction and diastolic relaxation times; and reduction of contractile reserve. Hyperthyroidism reduces serum cholesterol.

CLINICAL MANIFESTATIONS

Thyrocardiac crises are potentially seen without the complete picture of thyroid storm—in particular, without fever. Thyrocardiac crises otherwise can be divided into several major problems, including atrial arrhythmias and thromboembolism*^{376,380,399-410}; heart failure and manifestations of cardiomyopathy^{376,380,399-410}; the rare complications of conduction disturbance,⁴¹¹ ventricular arrhythmia,⁴¹² and sudden death⁴¹³⁻⁴¹⁵; and coronary artery spasm. Coronary artery spasm is increasingly recognized as a potentially reversible complication of uncontrolled hyperthyroidism, sometimes seen in young women, infrequently complicated by myocardial infarction.⁴¹⁶⁻⁴²⁸

APPROACH TO MANAGEMENT

If a thyrocardiac crisis is present, β -blockade is part of the therapy unless contraindications are present. In treating atrial fibrillation digoxin is used, and for congestive heart failure digoxin and furosemide are used. If some degree of systolic cardiac dysfunction may be present, β -blockade may result in hypotension and should be instituted with careful monitoring. For patients with tachycardia-related congestive heart failure, the use of beta blockers in doses equivalent to 20 mg propranolol every 6 hours may be well tolerated, and the dose may be titrated up to 40 or 80 mg every 6 hours. However, in low-output heart failure or heart disease of other causes complicated by hyperthyroidism, administration of beta blockers must be approached with caution if these agents are used at all.³⁸⁰ Diltiazem also must be used with caution because it may have negative inotropic effects. Thionamides should be given in relatively high dosage, such as such as 20 mg methimazole daily every 8 hours. Two hours after the first dose of methimazole, SSKI (potassium iodide oral solution) 5 drops every 6 hours may be started. Iodide is tapered to 2 drops three times per day before discharge and is discontinued after 7 to 14 days. Patients in atrial fibrillation resulting from hyperthyroidism generally should receive anticoagulation therapy according to the same criteria as other patients. For thyrocardiac crises, treatment with glucocorticoids is seldom indicated. A reduction of methimazole dose usually is indicated once the initial response is assured.

After medical stabilization, definitive therapy with radioactive iodine usually is offered to patients who have experienced thyrocardiac symptoms.³⁷⁸ Radiation thyroiditis or interruption of antithyroid medication to permit radioiodine administration can cause patient destabilization. Pre-treatment with thionamide medication usually should be offered for about 2 months in the absence of contraindications. For patients in atrial fibrillation, the frequency of spontaneous conversion to sinus rhythm is greater if

relatively large ablative doses of radioactive iodine are used, sufficient to bring about prompt development of hypothyroidism.³⁹¹ Thionamide therapy must be withheld temporarily to permit radioiodine treatment, but if antithyroid medication is reinstituted after radioiodine treatment, any recurrence of hyperthyroidism is usually corrected within 4 to 6 weeks.

Patients who do not spontaneously convert to sinus rhythm generally should be rendered euthyroid before elective cardioversion is attempted; otherwise, there is a greater risk of relapse of atrial fibrillation after cardioversion. It has been suggested that because no spontaneous conversions occurred more than 16 weeks after attainment of euthyroidism, the ideal timing for elective cardioversion is at that time.^{390,396} Hyperthyroid patients are more sensitive to warfarin than others. The immediate risks of anticoagulation sometimes must be weighed against the desirability of postponing elective cardioversion. The guidelines of the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy recommended that because the incidence of thromboembolic events in patients with thyrotoxic atrial fibrillation appeared similar to other causes of atrial fibrillation, antithrombotic therapies should be chosen based on the presence of validated stroke risk factors.³⁹⁸

In cases of anginal pain and coronary vasospasm, aggressive medical treatment of vasospasm and hyperthyroidism is indicated.

PROGNOSIS

Even in young adult patients, atrial fibrillation may be complicated by thromboembolism resulting in fatal or disabling cerebrovascular accidents.^{387,388,395}

About 37% to 61% of patients may experience spontaneous conversion of atrial fibrillation after attainment of euthyroidism, mostly within 6 weeks.^{377,390} Absence of congestive heart failure is a favorable prognostic predictor of spontaneous conversion. Other patients may be successfully cardioverted. The absence of other heart disease, short duration of atrial fibrillation, and younger age predict successful conversion and maintenance of sinus rhythm.

As a result of treatment of hyperthyroidism, a patient with heart failure caused by thyrotoxic heart disease experiences improved ability to augment cardiac output during exercise.³⁹⁹ With treatment of thyrotoxicosis alone, about 41% of patients with congestive heart failure and thyrotoxicosis who receive radioactive iodine experience relief of heart failure.³⁷⁷ For the rare patient having hyperthyroidism and anginal chest pain caused by coronary artery spasm, isolated published case reports emphasize reversibility of anginal symptoms after successful treatment of hyperthyroidism.

Lipid status should be reevaluated after correction of hyperthyroidism.

KEY POINTS

- In unstable patients, sampling of TSH, thyroid hormone concentrations, and any assessments of hormone binding should occur simultaneously.
- Low TSH is attributable to dopamine or glucocorticoid therapy in some critically ill patients.

*See References 308, 381, 382, 385, 387-398.

KEY POINTS (Continued)

- High free T_4 is attributable to furosemide, heparin, or sepsis in some critically ill patients.
- Thyroid function test abnormalities that resolve after recovery are common in critical illness (nonthyroidal illness syndrome).
- Low T_3 is the earliest finding of nonthyroidal illness syndrome, resulting from impaired peripheral activation of T_4 (impaired peripheral conversion of T_4 to T_3) and enhanced deactivation of T_3 (deactivating conversion of T_3 to T_2).
- Low transport protein concentrations, low total T_4 , and low TSH are seen in more longstanding or severe cases of nonthyroidal illness syndrome.
- Biochemical differentiation between nonthyroidal illness syndrome and intrinsic hypofunction of the pituitary or hypothalamus may be impossible until after recovery.
- Because it is unknown whether the changes of nonthyroidal illness syndrome are detrimental to the patient, the present-day standard of care does not require thyroid hormone treatment.
- T_3 has inotropic and vasodilatory effects.
- The rise of total T_4 and T_3 into the normal range that occurs during recovery from severe nonthyroidal illness syndrome may be accompanied by TSH elevation above the normal ambulatory range.
- Findings of low T_4 , low free T_4 , and high TSH generally signify hypothyroidism.
- Findings of high T_4 , high free T_4 , and low TSH generally signify hyperthyroidism.
- Among patients treated for established hypothyroidism, brief interruption of levothyroxine therapy confers negligible medical risk. Concomitantly administered substances may interfere with enteral absorption of levothyroxine. Conversion to intravenous administration of levothyroxine in the treatment of established hypothyroidism requires a dosage reduction.
- The patient having untreated hypothyroidism is at risk for hypoventilation, congestive heart failure, water intoxication, relative adrenal insufficiency, sensitivity to sedatives and analgesics, hypometabolism of administered medications, and resistance to warfarin.
- If replacement with levothyroxine is introduced too quickly, the patient having untreated hypothyroidism with coexistent heart disease is at risk for arrhythmia, exacerbated heart failure, or myocardial infarction.
- In the treatment of myxedema coma, the benefits of rapid replacement with levothyroxine outweigh the risks. Outcomes depend on additional supportive measures.
- Myxedema coma, thyroid storm, and thyrocardiac crisis are diagnosed by clinical evidence of the emergency condition and biochemical verification of thyroid status and are often appropriately treated in a critical care unit.

KEY POINTS (Continued)

- Clinical and biochemical control of hyperthyroidism should be attained before elective surgery.
- Coronary vasospasm may occur during hyperthyroidism and remit with control of hyperthyroidism.

ETHICAL CONSIDERATIONS

CONCEPT AND TERMINOLOGY OF IMPAIRED CONSCIOUSNESS

Alteration of consciousness is a frequent admission diagnosis to critical care services. Most patients require immediate and often extensive diagnostic workup as both time to diagnosis and treatment initiation are decisive factors for brain recovery. To the public, the portrayal of coma is overly optimistic as 89% of “comatose” patients in a meta-analysis of 64 characters in American soap dramas regained consciousness and around 92% “survived” coma.¹ In contrast, medical experience does not compare as favorably, as only about 50% of patients survive in an unselected coma population.²⁻⁴ Therefore, defining coma in a succinct and operational manner will provide a deeper understanding of the depth of brain injury and avoid miscommunications and unrealistic prognostications.

Consciousness can be viewed as the patient’s responses to internal and external stimulation and his or her awareness of self and the environment. These two basic components of consciousness, arousal and awareness, are clinically used to classify the state of consciousness, but, strictly speaking, the qualitative examination of arousal should be separated from the quantitative assessment of the patient’s self- and environmental awareness and cognitive function. These interdependent components are regulated by different neuroanatomic domains within the central nervous system. Arousal and ensuing wakefulness are tightly dependent on the network function of the ascending reticular activating system (ARAS), namely, the midbrain reticular formation, mesencephalic nucleus and tegmentum, thalamic intralaminar (centromedian) nucleus, and dorsal hypothalamus.

These build a network of brainstem and diencephalic centers with a strong connection to the cerebral cortices. Self-awareness and the spectrum of cognitive interactions with the environment are the purview of the hemispheres. Simplistically, the hemispheres are structured into three functional systems: units that receive, process, and store sensory information; units that generate and regulate motor activity; and units responsible for programming, regulating, and verifying actions. These three functional systems operate as an intercortical network; relate, as a whole, to the experience of awareness; and allow cognitive performance. The partition of arousal network and intercortical (cognitive) network implies that the level of self-awareness and cognitive performance cannot be examined in a patient with lack of arousal. In other words, in a person with a quantitatively reduced state of consciousness, the qualitative assessment of the content of consciousness is not possible. Practically speaking, the assessment of content (i.e., testing a patient’s cognitive abilities and thinking) should be done after the best level of arousal has been achieved. A fully aroused person can express completely normal or deficient awareness and cognitive performance. Conversely, failure of arousal renders it impossible to test awareness and cognition.

When evaluating a patient’s mental status, the state of consciousness should be viewed as a continuum ranging from the patient who has full alertness and cognitive lucidity to the deeply comatose patient; it is not an all-or-nothing phenomenon.⁵ An all-or-nothing approach limits the interpretation of remaining brain function and, hence, diagnostic certainty. Furthermore, the duration and time development of coma are helpful diagnostic features and should complement the quantitative and qualitative

assessment of consciousness. Standard classification systems categorize consciousness based on systematic testing of arousal, awareness, and content. [Table 61.1](#) classifies various abnormalities of consciousness, and the following section delineates clinically important syndromes.

In the *awake* state, the examination allows the clinician to test a person for the degree of self-awareness and intactness of cognitive function. Drowsiness, sleepiness, and *lethargy* resemble reduced spontaneous physical and mental activities in a person who cannot sustain wakefulness without repeated external stimulation. They are somewhat comparable to the experience of lighter sleep, though drowsy patients almost always have reduced attention and concentration and some degree of associated mild confusion. Although sleep and pathologic states of consciousness share common features—for instance, the sleeping person is unaware of his or her resembling unconsciousness—quick reversal to full consciousness is a classic feature of sleep.

A *stuporous patient* (from Latin *stupore*, meaning “insensible”) requires repeated, stronger stimuli to show some arousal, and these patients may or may not open their eyes. Full arousal and alertness are not achieved and with continuing external stimulation, restlessness and stereotypic motor responses are observed, but without the appropriate cognitive interactions. A deep stuporous state closer to coma is differentiated by European clinicians and is referred to as *sopor* (from Latin *sopor*, meaning “deep sleep”).

Coma (from Greek κόμα, or “deep sleep”) is a continuous state of unresponsiveness identified by an inability to arouse to vigorous (noxious) external or internal stimuli. The degree of coma can differ; lighter stages (sometimes denoted as semicoma) can be identified by brief moaning to strong stimulation and associated observed changes in autonomic function; whereas the deepest coma examination shows an absence of any response, including brainstem reflex responses (i.e., lack of oculo- and pupillomotoric responses). Some cyclic autonomic activity such as the sleep-wake cycle and changes in motor tone may coexist. A detailed discussion of coma is provided in the classic textbook by Plum and Posner.⁶

The *vegetative state* is characterized by the complete absence of behavioral evidence for self- or environmental awareness. This state can follow coma and identifies a state in which brainstem and diencephalic (thalamic) activity is present to a degree that clinical signs of spontaneous or stimulus-induced arousal and sleep-wake cycles are observed. Patients often show blink responses to light; intermittent eye movements (sometimes erroneously interpreted as following objects or looking at family members); stimulus-sensitive automatisms such as swallowing, bruxism, and moaning; or primitive motor responses. If this state lasts longer than 30 days, it is referred to as persistent vegetative state (PVS) and is used as a descriptive clinical syndrome rather than a disease-specific entity. The most common causes include cardiac arrest, head trauma, severe brain infections, and various causes of thalamic injury. Vegetative states can also be seen in the terminal phase of degenerative illnesses such as Alzheimer’s disease. Ambiguous terms for PVS such as *apallic syndrome* and *neocortical death* should be avoided.^{2,7}

Minimal conscious state can be diagnosed in patients displaying some but often inconsistent behavioral evidence of awareness of the environment, but they cannot

communicate their content and are unable to follow instructions reliably.⁸ It describes a large group of patients who are different from vegetative patients in that they demonstrate some signs of awareness of themselves and their surroundings, albeit inconsistently.

As mentioned earlier, the time progression and persistence of the impairment can be used to further classify abnormalities of consciousness. *Delirium* is classified as a mental disorder because it involves a fluctuating level of consciousness and pervasive impairment in mental, behavioral, and emotional functioning. It is commonly acute in onset and short in duration and is frequently correlated to a specific etiology such as medications, anesthesia, or sleep deprivation. The criteria for delirium listed in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) include a disturbance of consciousness with reduced the ability to sustain or shift attention and focus. In our experience, attention and concentration deficits are always present in delirious patients and accompanied by a variable degree of cognitive dysfunction unattributed to pre-existing dementia. The dysfunctions of this acute syndrome include memory deficits, disorientation, disturbance of language and situational perception, and disorganized behavior. Other delirium markers are its acute onset and tendency to fluctuate along a spectrum of hyperactive (i.e., agitation, restlessness, emotional lability), hypoactive (withdrawal, flat affect, apathy, decreased responsiveness), or mixed presentations. Concurrent or sequential appearance of features of both hyper- and hypoactive states is not unusual. The history, physical examination, and ancillary test results frequently indicate that the disturbance is caused by an underlying medical or situational condition.

Dementia is a chronic condition in which content of consciousness is affected initially, but in advanced stages reduced levels of arousal are seen. Dementia is generally progressive and affects memory and at least two other cognitive domains such as language, executive function, planning motor tasks, and recognition. Dementing illnesses include a variety of intrinsic degenerative diseases of the cerebral hemispheres, but they also result from many other causes such as traumatic brain injury and hydrocephalus. The underlying etiology can be reversible (i.e., after correction of a vitamin deficiency) or irreversible (Lewy body dementia). Additionally, disease progression can be highly variable, lasting weeks to years, often with fluctuating severity, or be static after the initial impact injury. Anxiety, depression, and agitation may alternate and greatly complicate the disease course. The anatomically affected neurologic structures are commonly a result of bihemispheric cortical dysfunction; however, subcortical structures (i.e., vascular dementia from multifocal small vessel disease) can also represent the predominant pathology.

Akinetic mutism is a silent, alert-appearing immobility of a patient with injury to the hypothalamus or basal forebrain. It manifests as apparent depressed levels of consciousness in a patient with well-formed sleep-wake cycles and with little or no evidence of awareness or spontaneous motor activity. Various etiologies can present or lead to an akinetic mute state, and it is imperative to have a rigorous neurologic examination and careful review of neuroimaging and electroencephalography (EEG). The term *locked-in syndrome* was introduced by Plum and Posner to describe the

Table 61.1 Classifications and Descriptions of Abnormalities of Consciousness

Consciousness (Arousal, Awareness)					Content and Cognitive Function	Involuntary Response			Main and Essential Dysfunctional Structure or System	
Terminology	Arousal (Level of Responsiveness to External Stimuli)		Awareness (Awareness of Self and Environment)			Brainstem Reflexes	Autonomic Reflexes	Auditory/Visual Response		Voluntary Response
Physiologic sleep	Normal with various degree of stimuli	Normal with various degree of stimuli	Normal with various degree of stimuli	Preserved	Preserved	Preserved	Preserved	Preserved	Preserved with various degree of stimuli	Normal
Dementia (subacute or chronic)	Normal to abnormal depending on disease progression	Normal to abnormal depending on disease progression	Normal to abnormal depending on disease progression	Variable impaired	Variable impaired	Preserved	Preserved	Preserved	Preserved until the damage is too extensive and severe	Cerebral cortex
Akinetic mutism or abulia (subacute or chronic)	Normal or depressed level, but hard to assess due to very slow response	Normal or depressed level, but hard to assess due to very slow response	Normal or depressed level, but hard to assess due to very slow response	Normal or depressed level, but hard to assess due to very slow response	Preserved	Preserved	Preserved	Preserved	Impaired or very slow response or almost quadriplegic	Hypothalamic or basal forebrain injury

RAS, reticular activating system.

quadriplegia and anarthria resulting from the disruption of corticospinal and corticobulbar pathways, respectively. The extent of the deficits in patients with locked-in syndromes can vary, but these patients are aware of the environment and can hear and understand what is discussed around them. They may retain some ability of oculomotor (i.e., ability to open eyes) or other residual cranial nerve function. These patients are also anarthric or severely dysarthric with varying degrees of motor deficits ranging from complete quadriplegia to quadriparesis. As consciousness is preserved, communication is possible using vertical or lateral eye movements or blinking of the eyelid to signal yes/no responses. The majority of cases are caused by basilar artery occlusion leading to brainstem infarction in the ventral pons, yet numerous other etiologies have been described. *Abulia* (from the Greek meaning “lack of will”) is an apathetic state in which the patient is awake, has normal sleep-wake cycle, and is very slow to respond to stimuli. Mental function is usually normal when tested with sufficient stimulation. It is secondary to bilateral frontal lobe disease and in severe instances may mimic or progress to akinetic mutism.

NEUROANATOMY, NEUROTRANSMITTER, AND PATHOLOGY

Consciousness, which consists of three main parts, largely depends on the integrity of brain structure for arousal (Fig. 61.1). The ascending reticular activating system (ARAS) is the lowest order arousal system, consisting of a set of brainstem nuclei located within the brainstem and interconnected by neuronal circuits. The ARAS relays arousal signals to the more rostral thalami, which, in turn, act as hemispheric gatekeepers of arousal and regulate consciousness and sleep-wake transitions. In turn, thalamic activated cerebral cortices allow cognitive processing, which then determines the overall content of consciousness.⁶ Structural damage to or metabolic-chemical derangements of any or all of these elements will affect consciousness. Important components of the ARAS⁹⁻¹¹ include the midbrain reticular formation, mesencephalic nuclei (dorsal raphe nucleus,

pedunculopontine tegmental nucleus, locus coeruleus), and ventral tegmental areas. Those areas have rich connections to thalamic intralaminar nuclei and further frontally reaching projections to the tuberomammillary nucleus, lateral hypothalamus, and basal forebrain.

The ascending arousal system of the brainstem contains different neurotransmitter systems. Main cholinergic projections include the ascending mesopontine tegmental and basal forebrain pathways projecting to the thalami and to virtually all subcortical and cortical structures. These projections usually function as synaptic facilitators but at times can act as depressors of transmission.¹² Glutamate is the main transmitter influencing the firing patterns of tegmental cholinergic neurons.¹³ The adrenergic component of the ARAS is closely associated with the noradrenergic neurons of the midbrain locus coeruleus. It runs in parallel with cholinergic projections rostrally to the cortical areas but also descends caudally within the spinal cord.¹⁴ Hypocretin/orexin neurons within the hypothalamus activate both adrenergic and cholinergic pathways and coordinate activity of the entire ARAS system, enhancing complementary and synergistic control of arousal and locomotion.¹⁵ Histamine-releasing cells from the hypothalamus and tuberomammillary neurons are active during the qualitative activation needed for cognition and EEG activation, but they remain silent during sleep.¹⁶⁻¹⁸

The main inhibitor of the arousal system is γ -aminobutyric acid (GABA), without which normal sleep does not occur. The GABAergic circuitry is located in the midbrain and pons, but its activity is regulated and sustained by forebrain structures.¹⁹ It is thought that the GABAergic system's main function is to contain and channel the spread of arousal, both spontaneously and in response to a stimulus. GABAergic processes are responsible for the occurrence of paradoxical sleep (deep sleep characterized by a brain wave pattern similar to that of wakefulness, rapid eye movements, and heavier breathing but without motor responses). The name “waking neurons” has been given to the serotonergic dorsal raphe nucleus in the midbrain,²⁰ which receives convergent excitatory input from the noradrenaline, histamine, and hypocretin/orexin arousal systems^{21,22} as the main activator of the ARAS. Cortical signals that pass through the

Figure 61.1 Main centers involved in providing arousal and wakefulness and their respective predominant neurotransmitters.

striatum (caudate and putamen) are refined by the action of dopamine. Dopaminergic neurons are tonically active and stimulate or inhibit cortical neurons depending on various environmental influences (pain, hunger, etc.).^{23,24} It is thought that many sensory signals that reach conscious awareness pass through this basal ganglia loop with dopamine as the modulating neurotransmitter. Koch and colleagues suggested that coalitions of neurons compete to dominate conscious thoughts and activities at any given time point and, hence, dopaminergic innervation may facilitate the transient domination of conscious awareness by certain sets of neuron coalitions.²⁵ Therefore, it seems that arousal is an event with a defined time distribution, which is tightly orchestrated by a few key neurotransmitters. As we know, there is no singular “arousal neurotransmitter.”^{10,26}

PATHOLOGY SEEN IN PATIENTS WITH IMPAIRED CONSCIOUSNESS

There are four major pathologies that can cause severe, acute, and global reductions of consciousness.^{6,27} (1) One of these pathologies is the presence of diffuse, global, or extensive multifocal bilateral dysfunction of the cerebral cortex. In this injury mechanism, the cortical gray matter is diffusely impaired and so are cortical-subcortical excitatory feedback loops. The clinical examination will reveal disinhibited autonomic brainstem reflexes, which have also been described as “reticular shock.” (2) Another is injury to the paramedian gray matter from the level of the nucleus parabrachialis of the pons (tegmentum) and reaching to the midbrain pretectal areas and ventral posterior hypothalamus. An injury of this type damages the ascending arousal system and normal cortical activation. The affected structures are predominantly the paramedian gray matter, extending rostrally from the level of the nucleus parabrachialis of the pons (tegmentum) and reaching rostrally as far as the adjacent pretectal area and ventral posterior hypothalamus. (3) The widespread disconnection of the cortex from subcortical activating mechanisms acts pathophysiologically to produce effects similar to both of the previously mentioned conditions. (4) Finally, cortical and subcortical arousal mechanisms can be affected by a variety of diffuse disorders and to various degrees—for example, metabolic encephalopathy in a patient with acute liver failure.

APPROACH TO COMA

The initial approach to stupor and coma is based on the principle that all alterations in arousal are acute, life-threatening emergencies. Urgent steps are required to prevent or minimize permanent brain damage from reversible causes. Patient evaluation and treatment must occur simultaneously. Serial examinations with accurate documentation are necessary to determine a change in the patient's status. Accordingly, management decisions (therapeutic and diagnostic) must be made. The clinical approach to an unconscious patient entails the following steps: (1) emergency treatment; (2) history (from relatives, friends, and emergency medical personnel); (3) general physical examination; (4) neurologic profile, the key to categorizing the nature of coma; and (5) specific management.

EMERGENCY MANAGEMENT

Initial assessment must focus on vital signs to determine appropriate resuscitation measures; diagnostic processes can occur later. Urgent and sometimes empiric therapy must be given to avoid additional brain insults.

OXYGENATION AND INTUBATION

Oxygenation must be ensured by establishing an airway for ventilation of the lungs. The threshold for intubation should be low in a comatose patient, even if respiratory function is sufficient for proper ventilation and oxygenation. The level of consciousness may deteriorate, and breathing may decompensate suddenly and unexpectedly. An open airway must be ensured and protected from aspiration of vomitus and blood. If severe neck injury is a possibility or has not been excluded, intubation should be performed by the most skilled practitioner without extension of the patient's neck. Mask-bag-assisted ventilation should continue during the examination if necessary. Signs of arousal include dilated, reactive pupils, copious tears, diaphoresis, tachycardia, and systemic hypertension.

A brief neurologic examination is mandatory before any sedative or paralytic required for intubation is administered. The key points of a rapid neurologic examination are the following:²⁸

- Assessment of level of arousal and level of consciousness (i.e., coma, stupor, lethargy)
- Pupillary size and response to light
- Abnormalities of eye movements (i.e., disconjugate eyes; unilateral gaze paralysis; lack of voluntary movements)
- Grimacing and motor responses to noxious stimulation
- Abnormal plantar response (Babinski's sign)

The preferred route of emergency intubation is orotracheal, which can be performed rapidly, safely, and reliably with inline stabilization of the neck in patients with suspected cervical spine injury. Intubation causes intense reflexive cardiovascular stimulation that may lead to a deleterious elevation of intracranial pressure (ICP). Therefore, the patient should be adequately sedated. Etomidate is the preferred sedative in patients with suspected ICP elevation as it reliably facilitates induction in less than 1 minute with a duration of action of 4 to 6 minutes. Propofol is another anesthetic agent that does not increase ICP; however, its hypotensive effects, which can ultimately decrease cerebral perfusion pressure, often limit its use. Both medications result in a dose-dependent decrease of cerebral metabolic rate that reduces cerebral blood flow and ICP. Ketamine has a fast onset, but it may elevate ICP and should generally be avoided. Midazolam can alter the patient's mental status and may prohibit a postintubation examination.

RESPIRATION/PEEP

The effect of positive end expiratory pressure (PEEP) on ICP is only partly predictable for a number of reasons. Lung and pleural pressures are transmitted to the cerebrospinal fluid (CSF) column through intravertebral spaces and the vertebral venous plexus, and to the jugular venous system through the superior vena cava. The effect of PEEP on ICP depends on both intracranial and pulmonary compliance

and changes over time. ICP responses are not limited to PEEP but also relate to mean airway pressure, which can be elevated by many factors other than PEEP, including peak airway pressure and inspiratory time. Furthermore, the position of the patient's head and upper body can significantly affect ICP. A nasogastric tube should be placed to facilitate gastric lavage, decompression, and to reduce the risks for aspiration.

CIRCULATION

Circulation must be maintained at a level always ensuring adequate cerebral perfusion pressure. In any patient with suspected brain injury, resuscitation fluids include isotonic solutions such as normal saline or lactated Ringer's solution. An initial systemic mean arterial pressure (MAP) of approximately 100 mm Hg is adequate and safe for most patients (unless intracranial bleeding is suspected). Because cerebral perfusion pressure (CPP) equals the difference between MAP and ICP, CPP-matching ICP therapy targets a CPP from 60 to 70 mm Hg in most instances. Invasive ICP monitoring is mandatory if ICP elevations are suspected. While obtaining venous access, blood samples should be collected for anticipated tests. Hypotension may be treated by replacing blood and volume losses and vasoactive agents may be utilized (if volume and cardiac status is adequate) to maintain target MAP and systolic blood pressures. Hypertension should be aggressively managed with intravenous antihypertensive agents that do not elevate ICP by their vasodilatory effects. Thus labetalol and nicardipine are generally preferred and commonly used for managing uncontrolled hypertension. In most cases, including patients with intracranial hemorrhage, systolic and diastolic blood pressures of less than 160 mm Hg and 90 mm Hg, respectively, are tolerated and maintained. Urine output should be at least 0.5 mL/kg/hour and accurate measurement requires bladder catheterization.

GLUCOSE AND THIAMINE

Hypoglycemia is a frequent cause of altered consciousness and also leads to secondary brain injury if uncorrected. Glucose (25 g as a 50% dextrose solution) should be administered intravenously and immediately after blood is drawn for baseline values, as the benefits of empiric glucose in preventing possible hypoglycemic brain damage outweigh the risk of hyperglycemia. Thiamine (100 mg) may be given with the glucose infusion to prevent precipitation of Wernicke's encephalopathy as seen in malnourished, thiamine-depleted patients receiving glucose infusions. In rare circumstances, an established thiamine deficiency can cause coma.

SEIZURES

Repeated generalized seizures such as impact seizures invariably lead to secondary brain injury and should be treated aggressively with an intravenous benzodiazepine. Lorazepam, in 4-mg doses administered at 2 mg/min, has become the preferred agent due to its longer duration of action; however diazepam and midazolam are effective alternatives. Subsequent seizure control is maintained with an intravenous antiepileptic. Although there is no proven drug of choice, first-line agents generally include phenytoin (15 to 20 mg/kg intravenous (IV) bolus at a maximum rate

of 50 mg/min), fosphenytoin (15- to 20-mg PE/kg IV bolus at a maximum rate of 150 mg/min), or valproic acid (20- to 40-mg/kg IV bolus). Fosphenytoin is often selected due to its faster rate of administration and lower risk of hypotension (as it is not formulated with propylene glycol). Drug levels for these agents should be drawn following the loading dose and maintenance dosing should be initiated. Corrected total target levels for phenytoin (and fosphenytoin) are 15 to 20 mcg/mL; free levels can be drawn in patients who are critically ill or have low protein stores with a target of 1.5 to 2 mcg/mL. Valproic acid target levels are 50-100 mcg/mL. Seizure breakthrough requires immediate administration of benzodiazepines and loading of a second anticonvulsant. Continuous video EEG monitoring is frequently employed to detect nonconvulsive seizures.

SEDATION AND PARALYSIS

Sedation is often required to facilitate comfort with respiratory support, to counteract agitation, or to treat elevated ICP. Short-acting medications given as continuous infusions such as propofol or dexmedetomidine are preferred. However, deeper sedation, especially in patients with seizures, may require a midazolam infusion. Because of the accumulation of its active metabolite in patients with renal dysfunction, extended durations of midazolam should be avoided or interrupted if possible. Sedation should be titrated to a predefined goal using a validated sedation scale. The Richmond Agitation Sedation Scale (RASS) is commonly used and a goal range of 0 (alert and calm) to -2 (light sedation, briefly awakens with eye contact to voice) is appropriate for most patients. Hourly interruption of sedation is needed to obtain serial neurologic examinations, except in paralyzed patients or those in whom awakening leads to deterioration of ICP. Additional analgesia (i.e., intravenous intermittent morphine [2 to 4 mg every 3 to 4 hours] or a fentanyl infusion) is often needed in postoperative patients or patients with traumatic injuries. Patients with critically high ICP should be paralyzed as part of the treatment regimen for increased intracranial hypertension, but only after initiation of both a sedative and analgesic.

REVERSAL OF DRUG OVERDOSE

Drug overdose is the largest single cause (30%) of coma in the emergency department. Most drug overdoses are treated by supportive measures alone. Certain antagonists, however, specifically reverse the effects of coma-producing drugs. Intravenous naloxone (0.4 to 2 mg) is used as "test" antidote for opiate-induced coma, and it acts as a μ -receptor antagonist. Caution is needed as the reversal of narcotic effect may precipitate acute withdrawal in an opiate addict. In suspected opiate coma, the minimum naloxone dose (not completely reversal) should be given to establish the diagnosis by pupillary dilation and to reverse depressed breathing and consciousness. Due to its short half-life, patients who respond to naloxone reversal may require additional doses or a continuous infusion to avoid rebound sedation and respiratory depression. Intravenous flumazenil antagonizes benzodiazepine-induced coma and can be administered in 0.2-mg doses every minute for a maximum of 1 mg. In patients who initially respond to flumazenil reversal but experience recurrent sedation, flumazenil 1 mg may be redosed every 20 minutes with a max of 3 mg/hour.²⁹

Careful consideration should be given prior to administration of flumazenil as patients may experience benzodiazepine-withdrawal seizures. Thus, whereas naloxone is commonly used with minimal serious adverse effects, the use of flumazenil should be restricted to select, low-risk cases. The sedative effects of drugs with anticholinergic properties, particularly tricyclic antidepressants, can be reversed with 1 to 2 mg physostigmine intravenously (duration of action about 45 to 60 minutes). Pretreatment with 0.5 mg atropine will reduce the risk for symptomatic bradycardia. Of note, only full awakening is characteristic of an anticholinergic drug overdose because physostigmine has nonspecific arousal properties.

BODY TEMPERATURE

Hyperthermia is detrimental in brain injury as it increases brain metabolic demands and facilitates secondary brain injury.³⁰ Elevated temperature greater than 104°F (40°C) requires immediate, lifesaving cooling measures, even before the underlying cause is determined and treated. In 2002, two research groups independently published that lowering the body temperature to 33°C for 12 or 24 hours in comatose survivors of cardiac arrest resulted in nearly doubling the number of patients being discharged home or to rehabilitation. Generally speaking, no patient with acute brain injury should be allowed to be hyperthermic, and modern technology provides a variety types of noninvasive and invasive cooling equipment suitable to maintain any target core temperature desired. Core temperatures of less than 93°F (34°C) on admission should be slowly elevated to above 35°C to reduce the risks of unwanted side effects from uncontrolled, persistent hypothermia.

HISTORY

Once the patient's condition and vital signs have been stabilized, clues to the cause of coma should be sought by interviewing relatives, friends, bystanders, or medical personnel who may have observed the patient before or during the decline in consciousness. The history should address witnessed events, evolution of coma, recent medical and surgical histories, and medication/drug intake.

PHYSICAL EXAMINATION

A systematic, detailed examination is necessary when approaching a comatose patient (Box 61.1, Table 61.2). Important findings include evidence of trauma, acute or chronic medical illnesses, ingestion of drugs (needle marks, alcohol breath), and the presence of nuchal rigidity.

As outlined earlier, an in-depth physical and neurologic examination followed by serial neurologic evaluations (i.e., hourly) is the most important, indispensable, and readily available method of assessing a comatose patient.³¹ However, in coma patients the examination remains limited in detecting changes in brain function. Nevertheless, the astute clinician will carefully evaluate for changes in findings (i.e., the appearance of new asymmetry in examination or focal deficits, progressive loss of brainstem reflexes, or loss of reflex motor responses). Finding progression of impairment is of immense clinical value as it indicates a new or worsening "intracranial emergency" demanding immediate clarification and stabilization. Skilled neurologic

examination is challenging and provides a limited surveillance window of brain tissue at risk. Intracranial monitoring and, if needed, repeated head imaging have become the standard of care in neurocritical care units.

The differential diagnosis of a comatose patient is supported by the patient's risk factor profile, activity at symptom onset, and disease progression. Acute, devastating headaches with nausea and vomiting quickly followed by impaired consciousness in a hypertensive patient with a history of smoking should be rapidly worked up for subarachnoid or intracerebral hemorrhage. Deterioration of consciousness hours after head injury necessitates immediate exclusion of newly emerging, delayed intracranial hematoma with intracranial pressure crisis. In contrast, the slow progression of a focal neurologic deficit evolving to generalized depressed consciousness in an elderly individual directs toward an intracranial metastasis with secondary seizures. Increased intracranial pressure is a common denominator of many acute and subacute central nervous system (CNS) injuries. Typical manifestations include headaches from the dural stretch of trigeminal (V) sensory fibers; intractable nausea and recurrent vomiting often associated with visual disturbances; some neurologic deficits on detailed examination; and, in later stages, reduction in level of alertness.

When performing the neurologic examination, monitoring vital signs can be utilized as part of the autonomic nervous system evaluation. For example, appearance of systolic hypertension, vagal bradycardia, and respiratory irregularity is known as Cushing's triad and indicates increased ICP. In addition, changes in the pattern of respiration in a spontaneously breathing patient can help localize the level

Table 61.2 Correlation Between Levels of Brain Function and Clinical Signs

Structure	Function	Clinical Sign
Cerebral cortex	Conscious behavior	Speech (including any sounds) Purposeful movement Spontaneous To command To pain
Brainstem activating and sensory pathways (reticular activating system)	Sleep-wake cycle	Eye opening Spontaneous To command To path
Brainstem motor pathways	Reflex limb movements	Flexor posturing (decorticate) Extensor posturing (decerebrate)
Midbrain CN III	Innervation of ciliary muscle and certain extraocular muscles	Pupillary reactivity
Pontomesencephalic MLF	Connects pontine gaze center with CN III nucleus	Internuclear ophthalmoplegia
Upper pons CN V CN VIII	Facial and corneal Facial muscle innervation	Corneal reflex-sensory Corneal reflex-motor response Blink Grimace
Lower pons CN VIII (vestibular portion) connects by brainstem pathways with CN III, IV, VI Pontomedullary junction pressure	Reflex eye movements Spontaneous breathing Maintained blood pressure	Doll's eyes Caloric responses Breathing and blood pressure do not require mechanical or chemical support
Spinal cord	Primitive protective responses	Deep tendon reflexes Babinski response

CN, cranial, nerve; MLF, medial longitudinal fasciculus.

of injury. Abnormalities of respiration can range from apnea to hyperpnea with undulating crescendo-decrescendo patterns as well as complete irregularity of breathing with erratic pauses that finally terminate in complete apnea. This “autonomic survey” and observing for spontaneous patient movements are followed by the assessment of a patient’s level of arousal. The reduction in response to external stimulations provides the basis for commonly used classification schemes such as the Glasgow Coma Scale (GCS). If the patient’s level of alertness permits, then orientation, attention and concentration span and intactness of cognitive functions are examined next. This is followed by a detailed assessment of cranial nerve, motor, and peripheral reflex status. Optic nerve head edema (papilledema) is an important and, if present, a reliable manifestation of raised ICP. Additional findings of increased ICP on fundoscopy include venous engorgement, loss of venous pulsation, optic disk hemorrhage with increased disk diameter, and blurring of its margins. Compression of the third nerve is a result of a variety of intracranial processes, including uncal herniation and aneurysms of the posterior communicating artery. It is identified by pupillary dilatation, ptosis, and various degrees of ophthalmoparesis except for abduction and intorsion-depression. A sixth nerve palsy, typically a nonlocalizing sign, is identified by abduction deficit and is seen in patients with elevated ICP or hydrocephalus and stretching of the nerve but is also present in patients with intrinsic brainstem injury (i.e.,

strokes). Patients with acute intracranial mass lesions and increased ICP commonly develop herniation syndromes—that is, shifting of brain tissue from areas with higher regional ICP toward areas with normal ICP. If the mass lesion is predominantly located within one hemisphere, the main force vector will shift the brain primarily laterally across the midline and toward the opposite hemisphere as it impresses on the upper brainstem and thalamic structures during lateral displacement. More centrally located mass lesions (i.e., acute, obstructive hydrocephalus or global brain swelling as seen in fulminant encephalitis or hepatic encephalopathy) will to the contrary lead primarily to downward herniation with the main force vector impressing upon the brainstem. Different herniation syndromes have different clinical presentations and therapeutic approaches. When intracranial hypertension remains uncontrolled and escalates uniformly central, downward herniation occurs involving increasingly more brainstem structures in a rostrocaudal fashion. The terminal event is complete brainstem destruction resulting invariably in brain death. During this course, progressive loss of brainstem reflexes can be determined on examination and at this stage, the patient is deeply comatose. Injury to the fifth cranial nerve nucleus within the pons results in loss of the corneal reflex. A vestibulocochlear nerve nucleus compromise results in loss of the oculocephalic reflex and manifests as “doll’s eyes” or the inability to maintain eye position as the head moves. Medullary injury with damage to the

ninth and tenth nerves results in loss of lower cranial nerve reflexes including the absence of gag and cough reflexes.

Ipsilateral hemiparesis indicates the possibility of uncus herniation causing compression of the contralateral cerebral peduncle as temporal lobe tissue herniates into the space between the tentorium and brainstem. For example, a left-sided subdural hematoma causing temporal herniation pushes the opposite cerebral peduncle and its motor fibers against the right tentorial edge (right-sided Kernohan's notch) leading to a hemiparesis on the same side as the hemispheric lesion. Posturing is involuntary flexion or extension of the arms or legs spontaneously or elicited by stimulation, and it is included in the Glasgow Coma Scale as a measure of the severity of brain injury. Three types of posturing can be observed depending on the level of brain injury: decorticate (flexor), decerebrate (extensor), and opisthotonos (body arching along the craniospinal axis) posturing. Injury involving the brainstem above or below the red nucleus in the midbrain leads to decorticate and decerebrate posturing, respectively. Of note, flexion or extension can be witnessed either unilaterally or bilaterally, is sometimes seen only intermittently, and can involve one or all extremities. Decorticate posturing commonly indicates damage of the cerebral hemispheres, the internal capsule, and the thalamus, possibly also involving the uppermost brainstem. Decerebrate posturing is involuntary extension of both upper (elbow) and lower extremities indicating brainstem damage below the midbrain. Progression from decorticate to decerebrate posturing is indicative of progressive transtentorial herniation. Opisthotonic posturing is an infrequently encountered sign seen with severe brainstem injury or extrapyramidal lesions involving the axial muscles. Importantly, increasing downward pressure leads to dysfunction first at the level of the diencephalon (i.e., thalamus), next affecting the upper and middle sections of the brainstem (midbrain and pons), and ultimately impeding medullary function leading to deep coma without any reflexes or motor responses (flaccidity). Once complete rostrocaudal herniation has occurred, the patient is brain dead.

ASSESSMENT OF COMA: GENERAL ASPECTS

Correctly characterizing disorders of consciousness continues to pose interesting clinical questions and diagnostic challenges with important ethical consequences (Box 61.2). Not only may an individual patient acutely fluctuate in his or her examination findings, but recovery may take place over prolonged time periods, necessitating constant reassessments. To address this uncertainty, standardized neurobehavioral assessments have become the best tool for categorizing coma and its transitional stages. Predicting long-term outcome has significantly improved when utilizing standardized assessments. Generally speaking, clinical and electrophysiologic markers of coma and its transitional states remain unsatisfactory. The reader is reminded that larger observational studies identified a high rate of misdiagnoses (>40%),³² especially in patients in vegetative state, when assessment is made on clinical grounds only.

Box 61.2 Characteristics of Categories in Coma

Supratentorial Mass Lesion Affecting the Diencephalon/Brainstem

Initial focal cerebral dysfunction
Dysfunction progresses rostral to caudal
Signs reflect dysfunction at one level
Signs often asymmetric

Infratentorial Structural Lesion

Symptoms of brainstem dysfunction or sudden onset coma
Brainstem signs precede/accompany coma
Cranial nerve and oculovestibular dysfunction
Early onset of abnormal respiratory patterns

Metabolic-Toxic Coma

Confusion/stupor precede motor signs
Motor signs usually symmetric
Pupil responses generally preserved
Myoclonus, asterixis, tremulousness, and generalized seizures common
Acid-based imbalance common with compensatory ventilatory changes

Psychogenic Coma

Eyelids squeezed shut
Pupils reactive or dilated, unreactive (cycloplegics)
Oculocephalic reflex unpredictable; nystagmus on caloric tests
Motor tone normal or inconsistent
No pathologic reflexes
Awake-pattern EEG

EEG, electroencephalogram.

STANDARDIZED NEUROBEHAVIORAL ASSESSMENT

The behavioral diagnosis of the level of consciousness in severely brain-damaged patients remains challenging. To improve differential diagnostic evaluations, evidence-based recommendations endorse neurobehavioral characteristics using standardized tools.³³ The Coma Recovery Scale-Revised (CRS-R) has excellent content validity and is a solid tool addressing all established differential diagnostic criteria. To differentiate vegetative, minimally conscious state (MCS) or emerging MCS, several other tools have demonstrated good validity, including the Sensory Modality Assessment Technique (SMART), Sensory Stimulation Assessment Measure (SSAM), Wessex Head Injury Matrix (WHIM), and Stimulation Profile (WNSSP). The FOUR and CRS-R tools showed substantial evidence of good interpreter reliability. Our recommendations are to use the Coma Recovery Scale-Revised (CRS-R)³² as a valid and reliable tool in most situations for differential diagnostic assessments. With reservations, the SMART, WNSSP, SSAM, WHIM, and DOCS can be used. The lack of evidence with respect to content validity, standardization, and reliability make the FOUR, INNS, Glasgow Coma Scale, Swedish Reaction Level Scale-1985, Loewenstein Communication Scale, and CLOCS undesirable.

NEUROIMAGING

Novel neuroimaging modalities have not only provided additional insight into residual brain function in patients with disorders of consciousness but have also raised ethical discussions concerning the clinical management of these patients. Neuroimaging studies have provided considerable evidence for the existence of major functional differences in patients with vegetative state (VS) and minimally conscious state (MCS).³⁴⁻³⁷ For example, positron emission tomography (PET) and functional MRI (fMRI) studies delineated more extended cerebral processing in response to various external stimuli of modalities in patients with MCS.^{35,36,38} Resting state fMRI studies identified that MCS patients have preservations of functional connectivity to higher-order associative cortices, such as default networks.^{37,39} Complementary to these results, brain tissue integrity, as assessed by diffusion weighted imaging and gray matter volumetry, is more preserved in MCS as compared to VS.^{34,40} These findings correlate to the relative improved long-term prognosis in MCS.⁴¹

Currently, MR imaging is the procedure of choice for structural and functional imaging of the brain. Further experience with MR tractography (DTI), estimating the extent of brain connectivity, and MR spectroscopy, evaluating regional neuronal chemistry, will enhance outcome predictions in patients with severe brain injury. In addition, passive, active-response, and resting-state functional MRI paradigms are currently being validated to help in differentiating impaired states of consciousness. The combination of clinical examination and standardized coma assessment with structural and functional imaging currently seems to provide the best estimates for long-term outcome.

CONVENTIONAL MAGNETIC RESONANCE IMAGING (MRI)

Commonly available morphologic MRI acquisitions include non-contrast-enhanced sagittal T1, axial diffusion, axial fluid attenuated inversion recovery (FLAIR), axial T2, coronal T2* (or gradient echo [GRE]) sequences as well as 3D T1-weighted volume acquisitions.

FLAIR and T2-SE sequences are commonly used to delineate, measure, and monitor the extent and impact of acute brain injury. Common pathologies seen include brain edema, contusions, intracerebral, dural or subarachnoid blood, herniation syndromes, and hydrocephalus. T2* (also called GRE) and susceptibility-weighted imaging (SWI) are helpful for delineating blood product and detecting hemorrhagic diffuse axonal injuries (DAI). In traumatic Brain Injury (TBI) patients, the total number of lesions detected on FLAIR and T2* has been shown to inversely correlate with admission GCS score.^{42,43} Three-dimensional rendering allows evaluating and quantifying brain atrophy after injury.⁴⁴ Conventional MRI is useful in TBI patients. Lesions in the pons, midbrain, and basal ganglia, especially when bilateral, correlate with poor outcome. However, the contrary may not be true as MRI may fail to explain why some vegetative state or marked cognitively impaired patients have minimal or no lesions. Further advanced imaging studies would be especially helpful for those patients (discussed later). Diffusion tensor imaging (DTI) can be viewed as an extension of diffusion-weighted imaging (DWI) where

diffusion restricted water molecule movement (i.e., water trapped in ischemic cells or, in DTI, confined to axonal spaces) is preferentially visualized. As with most conventional MRI techniques, obtaining results with DTI is independent of the coma or sedation status of a patient.⁴⁵ Serial changes in white matter DTI metrics can be used as surrogate markers to evaluate treatment responses even when clinical scores cannot be obtained.⁴⁶ Whole brain white matter and regional DTI measures have become sensitive markers of TBI impact correlating with acute and discharge injury severity, especially when adjusted for age, gender, and admission GCS score.^{47,48}

PROTON MAGNETIC RESONANCE SPECTROSCOPY (MRS)

MRS reveals noninvasively regional, metabolic information of targeted brain regions correlating with the functional neuronal state of the examined sample region. To assess brain function, comprehensive MRS protocols looking for changes in axial chemical shift imaging at the level of the cortical white matter,^{49,50} splenium,⁵¹ basal ganglia (thalamus),⁵² insular cortex, and pons⁴² have been used. Using this approach, it is possible to detect posttraumatic neurochemical damage and neuronal dysfunction in brain areas where conventional MR imaging techniques show no abnormalities.⁵³ In a TBI case-control study, the *N*-acetylaspartate (NAA)/creatinine (Cr) ratio correlated as a good neuronal marker with the overall recovery (and therefore lack as reliable index of unfavorable outcome after TBI), whereas less consistency was found using the choline (Cho)/Cr⁵⁴ or NAA/Cho ratios.⁵⁵ Moreover, early posttraumatic spectroscopic assessment of axonal damage is clinically relevant for prognostication, and significant increases in brain lactate levels seem to be a dependable index of injury severity and outcome in TBI.⁵⁶

POSITRON EMISSION TOMOGRAPHY (PET)

18-fluorodeoxyglucose (FDG)-PET delineates glucose utilization deficiencies and, hence, it provides insights to neuronal energy metabolism correlating to regional, functional performance. For example, in acute vegetative state, overall glucose utilization was significantly reduced to 50% to 70% in comparison with age-matched, healthy controls.⁵⁷ As expected, patients with locked-in syndrome (i.e., pontine lesions) showed normal cortical metabolism. TBI patients with diffuse axonal injury had neuronal hyperglycolysis and metabolic depression.⁵⁸ 1C-Flumazenil (FMZ)-PET measures the density of benzodiazepine receptors (BZRs) providing an estimate of neuronal integrity.¹⁵ O-H₂O PET imaging delineates activation-induced changes in regional cerebral blood flow in response to passive external (auditory, somatosensory or visual) stimulation. The combination of preserved activation of primary cortices (i.e., visual) but lack of co-activation of secondary processing areas provides evidence that “higher-order” associative cortical networks are disconnected from the primary sensory cortex.^{38,59-63} Thalamocortical disconnections have also been reported using this technique.⁶⁴

FUNCTIONAL MRI (fMRI)

Functional MR imaging provides activity measures of brain regions at rest and after both passive (internal,

though-induced) and active (external, command-induced) stimulation.⁶⁵ Such acquisitions can obtain estimates of average metabolic activity in relatively short time periods (i.e., 10 minutes) compared to PET (~30 minutes).⁶⁶ fMRI has been shown to be a good predictor of outcome in patients with impaired consciousness.⁶⁷⁻⁷² The previously discussed PET evidence of preserved but isolated (disconnected) cortical activation areas in a patients in vegetative state was corroborated by fMRI.^{39,73-76}

ELECTROPHYSIOLOGY

EEG

Although a single electroencephalography (EEG) study can be a helpful diagnostic tool (i.e., to identify seizures), diagnostic certainty improves with continuous or serial EEG monitoring. Reactivity that is the increase in brain wave frequencies with patient stimulation has been used to assess thalamocortical function. For example, a patient with renal or hepatic dysfunction may have slowed background rhythms with triphasic waves and preserved or absent reactivity. Cerebral hypoxia, drug intoxications, and sedative medications as well as other CNS depressants produce abnormal EEG patterns including burst suppression, alpha coma, and spindle coma. Focal EEG slowing with or without evidence of abnormal excitability (i.e., focal spikes) can be found in comatose patients with structural lesions, either focal cortical, focal deep-seated diencephalic or mesencephalic reticular formation, or diffuse bihemispheric. Furthermore, EEG is the primary diagnostic tool to identify patients with impaired consciousness due to nonconvulsive seizures or status epilepticus.

Interpreting EEG can be challenging for anyone not trained in neurophysiology. However, despite the numerous etiologies leading to coma, EEG in coma patients is dominated by a few stereotypic patterns generally providing good indicators of the depth of the coma. Separating three common themes of interpretations will aid the nonexpert in utilizing EEG for diagnosis and prognosis in patients with disorders of consciousness. EEG findings can be categorized into responsiveness (reactivity to acoustic, painful, and photic stimuli), brain wave frequency abnormalities (focal or global), and specific EEG patterns (i.e., seizure discharges). Keeping this categorization in mind, commonly encountered EEG findings will be discussed next.

In patients with *alpha coma* the underlying brain wave activity is predominantly in the (normal) alpha range, from 8 to 12 Hz. In contrast to the normal EEG in a healthy, awake person, the EEG pattern found in comatose patients lacks alpha reactivity, implying a significant disturbance of thalamocortical pathways. In 36 patients in alpha coma,⁷⁷ one third showed anterior predominance and two thirds (66%) showed uniform distribution of alpha activity. Three major brain-injury categories have been observed in alpha coma:^{78,79} status postcardiorespiratory arrest (anoxic encephalopathy), toxic encephalopathies, and de-efferentiated (locked-in) state (i.e., pontine hemorrhage).

Theta coma and *alpha-theta coma* patients show slower brain wave activities in the theta 4- to 7-Hz range (theta coma), which in some is superseded by a predominance of alpha activity (alpha-theta coma).⁸⁰ In many coma patients, the alpha and theta activities will change after about 5 days

to a more permanent pattern at which time the EEG may be uniformly slow and depressed. EEG reactivity may emerge in subsequent studies as a relatively favorable sign; however, resolution into a burst-suppression pattern without reactivity signifies unfavorable outcome after anoxic encephalopathy.⁸⁰

Beta coma consists of fast activities in the 12- to 16-Hz range, usually with frontal predominance. Interspersed alpha, theta, delta, and spindle (sleep)-like activities can be found. The most frequent cause for beta coma is sedative-hypnotic overdose from substances such as benzodiazepines and barbiturates.⁸¹

Intermittent rhythmic delta activity (IRDA) consists of low amplitude, slow 2- to 3-Hz sinusoidal waves. Those waves can appear intermittently during the early stages of impairment of consciousness and soon after loss of alpha rhythm.⁷⁸ This nonspecific pattern can be seen in many metabolic and toxic encephalopathies, hemispheric lesions, acute brain injuries, and other conditions affecting cortical and subcortical structures diffusely. The prognosis of IRDA depends on the underlying etiology.

Continuous high-voltage delta activity consists of arrhythmic, high-amplitude, polymorphic 1- to 2-Hz delta activity. This pattern is seen in later stages of coma and may evolve out of theta coma. This contrasts with the slow, nonreactive theta and delta coma EEG of low amplitude (<20 μ V) and without reactivity.

Spindle coma consists of an EEG pattern predominated by 11- to 14-Hz spindle discharges, which are generally symmetric and synchronous, appearing as sleeplike oscillations on a background rhythm dominated by theta and delta activities. It resembles the EEG of a sleeping person and additional findings include anterior, low-voltage rhythmic bursts, K complexes, vertex waves, and delta slowing. However, in these patients, wakefulness is not regained after stimulation and depth of consciousness does not fluctuate in spindle coma. These patterns indicate dysfunction at the brainstem level. Traumatic brain injury, anoxic encephalopathy, infectious encephalitis, drug-induced and metabolic encephalopathy, as well as postictal states can lead to this EEG finding.⁸²⁻⁸⁴ The prognosis of spindle coma is uncertain, as both positive⁸⁵⁻⁸⁷ and negative outcomes⁸⁴ have been reported.

Periodic lateralized epileptiform discharges (PLEDs) occur asymmetrically (lateralized) and are episodic in nature. Morphologically, variations include sharp waves, spikes, slow waves, or a combination of these followed by a slow wave with a periodicity ranging from 0.3 to several seconds.⁸⁸ PLEDs are nonspecific and can be seen in a wide variety of brain injuries such as after cortical ischemia and with brain tumors. They are also associated with recent seizures, alcohol withdrawal, and toxic-metabolic encephalopathy among many others.⁸⁹ In contrast, generalized periodic epileptiform discharges (GPEDs) are seen bilaterally and typically occur at a frequency of <1 Hz. Subclassifications define the interval between discharges and include periodic short-interval diffuse discharges (PSIDDs), periodic long-interval diffuse discharges (PLIDDs), and suppression burst patterns.⁹⁰ GPEDs are seen after global brain injury—for example, after hypoxic or hepatic encephalopathy, drug intoxication, but also with various degenerative disorders.⁹⁰

Bilateral independent periodic lateralized epileptiform discharges (BIPLEDs) are slow (<1 Hz), bilateral independent epileptiform activity⁹¹ seen in coma due to bihemispheric lesions. For example, after anoxic encephalopathy and infections, they are associated with a poorer prognosis⁹¹ and about two times higher overall mortality than patients with PLEDs.^{91,92}

The *burst-suppression* pattern identifies an EEG demonstrating generalized, synchronous bursting of slow but mixed-frequency waves of high-voltage alternating periodically interspersing within longer periods of isoelectric (flat) EEG. It identifies abnormal cortical excitability,⁹³ and with deepening coma, the isoelectric periods become longer. Main etiologies include anoxic encephalopathy, severe intoxication, or sedative/anesthesia-induced coma states. The overall prognosis is determined by the underlying etiology.⁹⁴

Triphasic waves are distinct, blunt delta waves (~2 to 3 Hz) consisting of a high-voltage positive wave preceded and followed by lower amplitude negative waves. This nonspecific EEG can be seen in various brain injuries, among them serotonergic syndrome, Creutzfeldt-Jacob disease, lithium and baclofen toxicity, hepatic and renal insufficiency, and neuroleptic malignant syndrome.⁹⁵

Studies have identified that different EEG patterns seen in patients with hypoxic (postarrest) encephalopathy include suppression, burst suppression, alpha and theta coma, complete generalized suppression (<10 μ V), and generalized periodic complexes in combination with burst suppression. Unfortunately, common to all of them is the poor correlation to long-term outcome.⁹⁴

EVENT-RELATED POTENTIALS (ERPs)

These EEG potentials are identifiable after signal-averaging EEG-derived potentials evoked by a specific sensory, cognitive, or motor stimulus. Under normal circumstances, the brain generates event-related, neuronal (electrical) responses to stimulation. This neuronal activation can be detected by surface EEG; however, it requires specific mathematical processing of the EEG signal to identify brain oscillations that are time and phase locked to particular events (stimuli). Detection of such event-related potentials in patients with impaired consciousness has been interpreted as the brain's ability to process stimulus information and for cortical movement preparation. Advantages of this approach include detected signals that have an excellent time-stimulus correlation within the millisecond range helpful to relate a particular stimulus to certain cortical processing. The method is low cost and noninvasive, and it can be used to monitor the brain function. Fast processors have allowed the development of brain-computer interfaces based on event-related signal responses that assist communication with brain-injured patients. Several ERP paradigms have been developed allowing identification of specific response signals. The N1-P2 complex has been identified in visual ERPs and its presence interpreted as a negative correlation to repressiveness.⁹⁶ The P300 (or P3) is an average, positive potential with a latency of about 300 milliseconds. It is generated when a patient mentally reacts to a defined cognitive stimulus and is related to positive outcomes in coma.⁹⁷ Cognitive responses to command have been verified in patients with complete locked-in syndrome after basilar artery thrombosis.⁹⁸

EVOKED POTENTIALS

Brainstem auditory evoked responses (BAER) are a series of seven potentials recorded at specific time intervals at the skull after defined auditory stimulation employing headphones. Based on the redundancy and interconnections of the auditory pathways, BAER are robust and can be obtained in many patients with depressed level of consciousness, including patients under anesthesia or deep sedation. This implies that the absence of BAER, or its lemniscal complexes III-IV reflecting the integrity of upper brainstem, uniformly infers a poorer prognosis in coma (i.e., 3 to 6 days after head injury).⁹⁹ In addition, BAER have been employed as a "brainstem monitoring" tool to identify progressive downward brain herniation. Frequently, in clinical settings, BAER monitoring is combined with somatosensory evoked potential (SEP) and EEG monitoring. Somatosensory evoked potentials (SSEP) are a series of peaks recorded over the neck and scalp in response to electrical stimulation of a peripheral nerve, usually the median nerve. The N13 wave is a negative peak at 13 milliseconds reflecting activity at the cervical cord, whereas the N20 is a negative peak at 20 milliseconds reflecting the earliest cortical activity. Longer latency responses are also seen at 25, 35, 45, 70, and 95 milliseconds, reflecting higher cortical processing. Multimodality evoked potentials (MEP) combine simultaneous brainstem auditory, somatosensory, and visual evoked potential monitoring¹⁰⁰ in order to enhance the predictive value of evoked potential monitoring—for example, in TBI patients¹⁰¹ or during induced barbiturate coma where examinations cannot be obtained.¹⁰²

CEREBRAL BLOOD FLOW MONITORING

Transcranial Doppler (TCD) records the velocity and pulsatility of cerebral blood flow, allowing hemodynamic analysis, despite the use of sedatives or moderate hypothermia. TCD has been utilized for serial examinations in comatose patients after initial recovery from cardiac arrest in order to detect and treat early cerebral hemodynamic changes. If a patient has an appropriate temporal ultrasound window, TCD can determine cerebral perfusion arrest and, hence, can be used as an ancillary study to determine brain death.¹⁰³ Further, velocity and pulsatility indices correlate as a noninvasive measure with ICP elevations and also identify the delayed presence of a hyperemic flow pattern—that is, high velocities with low pulsatility as seen in patients with intracranial hypertension from hyperemia.¹⁰⁴

XENON-ENHANCED CT SCANNING

Xenon CT utilizes the diffusion of xenon into the CNS to determine cerebral blood flow (CBF)¹⁰⁵ in order to assess perfusion deficits after a traumatic brain injury.¹⁰⁵ Using hyperventilation, xenon CT can be used to estimate cerebral vasoreactivity, a marker correlating with outcome in comatose TBI patients.¹⁰⁶

GENERAL TREATMENT APPROACH

The immediate goals in a comatose patient are stabilization of vital signs, rapid diagnosis, immediate treatment to reverse the primary injury (i.e., recanalization of cerebral

blood flow), and minimization of further nervous system damage from secondary injury (i.e., brain swelling). These general goals are greatly facilitated by a team approach of medical and nursing staff with expertise in acute brain injuries. Successive care steps in managing coma of unknown etiology include (1) immediate exclusion of most harmful brain injuries (i.e., intracranial bleeding from an unsecured aneurysm), (2) sequentially ruling out alternative diagnoses, (3) determining the precise injury type leading to coma, (4) stabilization and reversal of primary brain injury, and (5) intensive brain monitoring (serial examinations, imaging, ICP, etc.) with watchful anticipation and early treatment of secondary injuries. It is of utmost importance to remember that the “time is brain” concept holds true for each of these care steps. Acute coma should be viewed as a “brain arrest” and approached with similar urgency and diligence as cardiac arrest.

If known, initial coma evaluation must take the injury mechanism into account. For example, in trauma victims, empiric cervical spine stabilization and early detection of an unstable c-spine injury by reconstructed cervical CT will be needed (i.e., before evaluating oculocephalic responses). Endotracheal intubation is frequently required due to the risk of aspiration and the need to maintain an open upper airway in an unconscious patient. Prehospital endotracheal intubation was associated with a significant decrease in mortality from 36% to 26% in patients with blunt injury and a GCS ≤ 8 , especially those with severe head injury by anatomic criteria.¹⁰⁷ Furthermore, mechanical ventilation is required to avoid oxygen desaturations (of the brain) or to induce therapeutic hypocapnia to acutely lower uncontrolled ICP. Early tracheotomy is often indicated in moderate to severe brain injuries. For example, a GCS of ≤ 4 on day 3 of injury or a Simplified Acute Physiology Score (SAPS)¹⁰⁸ of >15 on day 4 can indicate tracheotomy with 84% positive predictive value.¹⁰⁹ There are many benefits of early tracheotomy including increased patient comfort and subsequent reduction in sedatives and analgesics and ease of oral and pulmonary care, and its association with shorter duration of mechanical ventilation and ICU length of stay.¹¹⁰ At our institution we commonly perform bedside tracheotomy, which is a safe bedside procedure that circumvents the need to transport patients with brain injury and reduces overall costs.¹¹¹

Any correctable coma etiology such as abnormal glucose and electrolyte levels, hypotension, hypoxemia, or abnormal core temperatures should be managed immediately. Intravenous access is immediately established for the administration of resuscitation fluids, administration of contrast, and therapeutic care. Infusion of hypotonic solutions should be avoided to prevent deterioration of intracranial swelling, and there is a definite role for immediate ICP monitoring (i.e., using an external ventricular drain, which also allows the release of CSF) in any acute brain injury with the potential for ICP. The management of raised ICP is discussed in Chapter 16.

TRAUMATIC AND NONTRAUMATIC COMA

Coma is a descriptive term based on examination findings and can result from a range of heterogeneous etiologies that are classically grouped into traumatic versus nontraumatic coma. As outlined earlier, other stages of impaired

consciousness, including vegetative state, typically follow nonremitting acute coma. Usually after 1 month of coma, the term *persistent vegetative state* is used for both nontraumatic and traumatic etiologies; however, some authors prefer the term *permanent vegetative state* 3 months after nontraumatic and 1 year after traumatic injury. Notably, these terms do not imply irreversibility and do not exclude the potential for further recovery.¹¹²

Dividing coma into traumatic and nontraumatic etiologies is useful as each group is predominated by different demographics and disease prognosis. Often patients with traumatic brain injury achieve greater functional and cognitive improvements than patients suffering from acquired cerebrovascular or anoxic injury. In a longitudinal, prospective study of 192 traumatic, 104 cerebrovascular, and 33 anoxic brain injury patients, male gender was prevalent in all etiologies. Patients with traumatic brain injury were younger and had shorter admission/rehabilitation intervals, greater functional and cognitive outcomes, and a higher frequency of returning home. In contrast, patients with anoxic brain injury achieved the lowest grade of functional and cognitive recovery.

COMA AFTER SEVERE TRAUMATIC BRAIN INJURY

Therapeutic interventions following severe traumatic brain injury (TBI; GCS ≤ 8) should focus on blocking the primary injury process and preventing or reducing secondary brain injury. Primary injury in severe TBI includes hematoma formation, diffuse axonal injury after high-velocity injury (i.e., vehicle collisions, falls from great height), and ischemic brain injury due to traumatic vascular lesions (i.e., arterial dissection in the neck). Immediate arrest of ongoing primary injury (i.e., by acute recanalization of a dissected arterial occlusion or reversing anticoagulation during ongoing intracerebral bleeding) should be attempted whenever possible. Unfortunately, little can be done to treat or reverse the primary injury in TBI. Secondary brain injuries after TBI are common and include increased brain swelling leading to ICP elevations, brain tissue shifts (herniation) and critical reduction in cerebral perfusion pressure, formation of new hematoma, prolonged seizures, hypoxia, neurogenic/hypovolemic hypotension, uncontrolled hyperventilation, hypoglycemia, thromboembolism from venous thrombosis, and so on. Therefore, early TBI management strategies should focus on prevention and early recognition of such complications and a combination of intracranial (i.e., ICP, brain temperature, brain oxygen tension and perfusion) and systemic monitoring as well as repeated neuroimaging is indicated in the patients.

Noncontrast CT is the most common imaging evaluation tool in TBI patients. A cervical spine CT with reconstructed views and head and neck CT angiogram (CTA) are often added during initial evaluation, if injury to the neck and arteries, respectively, is suspected. Bone and brain windows should be reviewed separately and in experienced hands. Head imaging has a good sensitivity for the presence of pathologic air, skull fractures, hemorrhagic lesions, abnormalities of the brain parenchyma (i.e., shift), and obstruction of CSF spaces (hydrocephalus). Injury to the neuroanatomic structures of consciousness or the presence of additional etiologies for coma (i.e., alcohol) should be

considered when disparities between CT findings and examination exist. In this setting, appropriate additional screening and further imaging diagnostics (i.e., MRI) must be initiated.¹¹³ Compared to CT, MRI has a higher sensitivity to detect diffuse axonal injury (DAI); however, this advantage has not translated into improved clinical outcomes as there is currently no treatment for this condition. However, both the detection of DAI and delineating injury of major motor (i.e., corticospinal) tracts on diffusion tensor imaging (DTI) can be utilized together with the clinical course to prognosticate TBI.¹¹⁴ MR spectroscopy (MRS) provides additional “chemical” information, especially of the white matter injury process.¹¹⁵

The presence and severity of secondary brain injury should constantly be assessed and managed throughout the acute phase of TBI. Its time course can be variable but is somewhat predictable: for example, ranging from hours (i.e., development of new hematoma) to 1 to 3 days for brain edema development to several days as seen in late brain ischemia from vasospasm due to traumatic subarachnoid blood. There is only limited evidence to support the use of ICP monitoring. ICP monitoring has evolved as an essential tool and also one of the earliest monitoring tools in clinical practice; thus many believe clinical trials cannot ethically be justified. Current TBI management guidelines recommend its use in severe TBI. Of note, head imaging cannot predict ICP. Furthermore, treating for elevated ICP (other than empirically in the emergency setting) and not monitoring ICP can be deleterious and result in a poor outcome.¹¹⁶ In addition to ICP, other brain monitoring techniques utilized in modern TBI management include jugular venous and transcranial oxygen saturations (SjvO₂, NIRS), brain tissue oxygen tension (btO₂), brain tissue metabolism (microdialysis) and temperature, direct brain perfusion, transcranial Doppler sonography, and electrophysiologic studies such as EEG and evoked potentials. A discussion of these techniques is beyond the scope of this chapter and the reader is referred to recent reviews.

The management of severe TBI includes emergent decompressive craniectomy in controlling intractable ICP, especially if deterioration is associated with hematoma evacuation and there is some evidence that there will be positive outcomes in surviving patients.¹¹⁷⁻¹²⁸ Although timing of decompressive craniectomy remains controversial, early referral seems most intuitive. The Brain Trauma Foundation’s Guidelines for Management of Severe Traumatic Brain Injury regard craniectomy as an option after TBI to manage patients with intracerebral hemorrhage (ICH) and the resultant increased ICP refractory to medical management.¹¹⁶ Intravenous mannitol and hypertonic saline solutions are a main building block in the management of increased ICP.¹²⁹⁻¹⁴¹ The superiority of one over the other is uncertain, and both approaches are routinely used in the management of severe TBI.¹⁴² Therapeutic hypothermia is postulated to exert neuroprotective effects by several mechanisms, including reducing cerebral metabolic rate/requirement, modulating apoptosis or programmed cell death, reducing intracellular calcium/toxic excitatory neurotransmitters/inflammation, and preserving protein synthesis.^{116,143-151} However, the reported impact on neurologic outcome in severe TBI remains inconsistent and a meta-analysis of randomized controlled trials suggests its lack of

benefit in severe TBI.^{143,144} We utilize hypothermia as last resort therapy and commonly, together with pentobarbital therapy and ICP-matching, CPP elevation to protect the brain from otherwise intractable ICP elevations. Until well-designed, randomized controlled trials are available, its use must be weighed against potential side effects such as an increased incidence in pneumonia and coagulation abnormalities, among others.^{143,151}

The initial GCS seems to be a reasonable marker to predict mortality from severe TBI. To further improve prediction, models include a combination of clinical data, imaging results, GCS score, and patient demographics.¹⁵² In a large, traumatic coma databank study,¹⁵³ patients with severe injury (GCS 3 to 8) had approximately 36% mortality. In 170 patients, the GCS 5 hours postinjury was compared to the Glasgow Outcome Scale (GOS) at 1 month and positive recovery was seen in 99% of mild TBI (GCS 13 to 15), 71% of moderate TBI (GCS 9 to 12), and in only 35% of severe TBI. In contrast, only 2% to 3% of patients with mild TBI (GCS 13 to 15) died. Generally speaking, clinical outcome after TBI is more variable than in nontraumatic coma (i.e., after hypoxia).¹⁵⁴ Furthermore, outcome predictions for patients with intermediate GCS scores identify that a midline shift of less than 4.1 mm on initial CT scanning had a significantly higher favorable outcome rate compared with patients with a larger shift.¹⁵⁵

Biomarkers after traumatic brain injury (TBI), such as cellular glial fibrillary acidic protein (GFAP) and S100B released with astrocyte injury, may offer diagnostic and prognostic tools in addition to clinical indices. In 79 patients with TBI (GSC ≤ 12), identified intracranial mass lesion, pupillary reactivity, GFAP, and S100B were the strongest predictors of death and unfavorable outcome, with S100B as the strongest single predictor of unfavorable outcome with 100% discrimination.¹⁵⁶ Somatosensory evoked potentials in 58 TBI patients unconscious for >30 days were compared with outcome at 12 months¹⁵⁷ and showed an excellent prediction for outcome (persistent coma or MCS, 92% and 86%, respectively) at 12 months when combined with age, sex, and GCS.¹⁵⁷ Furthermore, among electrophysiologic testing, SEP and BAEP are more sensitive than EEG (i.e., 45% to 60% sensitive versus 35%) and if EEG and SEP show opposing results, generally speaking, prognosis is linked to the better test result.¹⁵⁸ The results of multimodality evoked potentials can be used as a reliable prognostic indicator (91% accuracy) in TBI patients.¹⁰¹

The International Mission for Prognosis and Analysis of Clinical Trials in TBI (IMPACT) is a prognostic model predicting 6-month functional outcome (Glasgow Outcome Scale [GOS]) and mortality in 587 patients with severe TBI (mean age 38 ± 17 years). At the 6th month, the median GOS was 3 (IQR 3) and 6-month mortality 41%, and age, motor score, pupillary reactivity, head CT findings, secondary insults, and laboratory values displayed good prediction ability for unfavorable outcome and mortality.¹⁵⁹ In another study of 428 isolated, older adult TBI cases, the in-hospital death rate was 28%, and increasing age, decreasing GCS, and injury type were significant independent predictors of in-hospital mortality. At the 6-month follow-up, age < 75 years and with systolic blood pressure (BP) on arrival at hospital of 131 to 150 mm Hg had higher likelihood of living independently at follow-up. No patients with a GCS <

9 had a favorable 6-month outcome, and most of them died, with the survival rate for brainstem injury at 21%.¹⁶⁰

COMA AFTER CARDIAC ARREST

Cardiac arrest affects more than 300,000 people each year in the United States alone and anoxic-ischemic encephalopathy is among the leading causes of mortality and morbidity. Since the publication of two pivotal trials in 2002 utilizing systemic cooling, the outcome for patients in coma after out-of-hospital ventricular fibrillation arrest has significantly improved. Simultaneously, prognostication after arrest in patients has become more complicated as the literature is lacking new prospective outcome studies integrating the advantages of hypothermia treatment.

The retrospective landmark study by Levy and colleagues,¹⁶¹ which reviewed postcardiac arrest outcome of 210 patients studied in the mid-1970s, is still commonly applied for prognostication. However, several inherent epidemiologic shortcomings of this study exist in addition to the fact that postcardiac arrest management has obviously advanced. The American Academy of Neurology published guidelines in 2006¹⁶² based on an in-depth review of the available literature; however, most studies included were performed without the use of hypothermia. The guideline defines poor outcome either as coma or death at 1 month or severe disability at 6 months. Further, the absence of brainstem reflexes or absence of extensor motor responses at 72 hours was shown to be highly specific (or have a false positive rate near zero) and so were absence of somatosensory evoked responses (SSEPs) and a high level of neuron-specific enolase (NSE).

Hypothermia has multiple actions not only within the CNS but also systemically. Among them are depression of neuronal activity, amelioration of intracellular postischemic reactions mitigating secondary cell injury, cardiac arrhythmias, hypocoagulability, decrease in immune defense, and reduction in drug metabolism and clearance. Notably, the latter can lead to misinterpretation of the prolonged effects of sedatives and paralytics. Therefore, interpretation of the neurologic examination and prognostication in patients undergoing hypothermia or rewarming is complex and challenging. Generally speaking and without the use of hypothermia, absence of brainstem reflexes implies that the cortex is severely affected as the brainstem neurons are more resistant to hypoxia-ischemia. Absence of pupillary reflexes at 72 hours predicts poor outcome with high specificity; however, the opposite, the presence of reflexive pupils, only predicts good outcome in about 21%. Studies performed after the introduction of hypothermia¹⁶³⁻¹⁶⁵ delineate predictive findings for absent pupillary responses but delineate that the corneal reflex seems to be more vulnerable to prolonged sedative and hypothermic effects. With respect to motor responses, studies performed prior to hypothermia identify a high predictive value for poor outcome for the absence of motor responses at 72 hours, a clinical finding that outperformed even SSEP prediction.¹⁶⁶ On the contrary, studies suggest that the lack of motor responses does not invariably predict poor outcome in patients treated with hypothermia (i.e., positive predictive values 92% and negative predictive value 85%) and exceptions have been reported.^{163-165,167}

Electroencephalography (EEG) is used in postcardiac arrest patients to determine outcome but also to differentiate myoclonus from shivering and detect seizures. Generalized EEG suppression, burst suppression with or without epileptiform activity, and a flat background with intermittent generalized periodic complexes are indicators of poorer prognosis. The opposite is true for finding reactivity and variability of the EEG pattern in patients treated with or without cooling. Larger prospective studies are currently lacking; however, some reports identify some hypothermia-treated patients with postanoxic status epilepticus who can achieve good outcome,¹⁶⁸ especially when the status evolves from a continuous EEG pattern and not from burst suppression.¹⁶⁹ As seizures and status epilepticus are seen in up to 65% of patients with less severe cortical damage, continuous EEG is indicated to guide management and prognostication in many postarrest patients.

According to current practice parameters from 2006, the absence of the N20 (primary cortical somatosensory) wave on SSEPs in the first 3 days after cardiac arrest identifies a high likelihood for poor outcome. In contrast, only about 41% of patients with present N20 wave will recover. Prognosticating based on SSEP findings in patients treated with hypothermia has only been reported in a few smaller studies with uncertain overall results^{170,171}; however, SSEP likely remains useful as evoked potentials are relatively resistant to metabolic and temperature derangements. Also, the NSE is a frequently used and validated biochemical marker used for prognostication. Levels >33 mcg/L at 72 hours or earlier were found to have zero false predictive rate in patients treated without hypothermia. However, hypothermia decreases NSE levels. Some studies have shown that a similar cutoff also holds true for the hypothermia-treated patient population,¹⁷²⁻¹⁷⁴ whereas others found unacceptable false-positive rates for the cutoff value 33 mcg/L.^{175,176} With respect to imaging, certain MRI findings such as severe cortical abnormalities on diffusion-weighted imaging have been shown to correlate to poor outcome,¹⁷⁷ but imaging studies often report on smaller patient numbers and are performed unblinded, reducing their value for prediction. Some studies identify that most patients who regained consciousness had normal cortical structures, some of them despite involvement of the deep gray nuclei.^{178,179}

Myoclonic status epilepticus are generalized, multifocal, repetitive muscle jerks involving some or all parts of the body. They are frequently seen within 24 hours after arrest, and EEG often shows burst suppression or bursts of generalized spikes. Whether myoclonic discharges actually represent seizures remains controversial, and as patients may have severe cortical damage and clinical myoclonus at the same time, it is postulated that myoclonus status epilepticus is subcortical in origin. In contrast, postanoxic status epilepticus is cortical in origin (but some overlap to myoclonic status may exist), whereas the posthypoxic myoclonus (Lance-Adams syndrome) is generally seen after primary respiratory failure. It is triggered by startle, often subsides over time, and the patient may be aware and distressed by it. Myoclonic status epilepticus has been associated with poor prognosis and remains poor even in the setting of hypothermia.^{163,165}

Given these results it seems prudent to forecast the postarrest patient treated with hypothermia 72 hours after the

event. Examination should take place at least 12 hours after termination of all sedatives and later if concomitant renal and liver damage are confounding factors. Prognostic variables associated with but not invariably predictive of poor outcomes are (1) absences of brainstem reflexes, (2) absence of motor responses or extensor posturing, (3) EEG abnormalities including generalized suppressions or periodic complexes on suppressed background and a burst suppression pattern with generalized epileptiform activity, (4) myoclonic status epilepticus, (5) MRI with widespread cortical injury on DWI or CT with loss of gray-white matter differentiation and sulcal effacement, (6) high NSE levels, and (7) absence of N20 on SSEP.

ETHICAL CONSIDERATIONS

A surrogate decision maker is a person who directs care when the patient is unable to provide consent. Legally and ethically, surrogate decisions should follow the expressed wishes of the patient. In the absence of known prior wishes, surrogates should utilize the best standard with respect to what the patient would do when confronted by the circumstance. A surrogate designated by the patient has precedence over other potential decision makers and is delineated by an advanced directive, also called a health care proxy, health care agent, or durable power of attorney for health care. In contrast, a living will expresses patient preferences but does not authorize a surrogate decision maker or spokesperson. If there is no designated surrogate, family members and close friends are selected in order of their relationship to the patient; the highest priority is given to the spouse, then parents, then children, then siblings followed by other relatives and finally friends. In a comatose patient, surrogates or family members may authorize a do not resuscitate (DNR) order or request limitations of care (i.e., no hemodialysis). Approximately two thirds of DNR orders are put into place by surrogate decision makers.¹⁸⁰

It is important to strive for the best possible diagnostic and prognostic correctness when discussing a DNR order or withdrawal of care. Understandably, relatives and surrogates place a great deal of decision making on the significance of conscious experience and the level of expected patient interactions with the environment (recovery). Therefore, the diagnostic accuracy of a patient's present level of consciousness is requested from the treating physician as well as the best estimate of improvement of consciousness.¹⁸¹ Identifying medical futility in a patient with markedly impaired consciousness allows the surrogate and physician to withdraw life-supporting therapy. However, surrogate decision making may change if a patient is in a minimal conscious state, as this disorder implies different prognostication, especially in TBI patients.¹⁸² Further, it is important for physicians to reiterate to the family that coma progression into the vegetative state is not considered an improvement. This progression is seen in most coma patients and sleep-wake cycles, roving eye movements, startle, and other witnessed phenomena are merely reflexive and do not indicate consciousness or awareness. Of note, "persistence" is a diagnosis given to a patient who remains in a vegetative state for greater than 1 month. This state is considered permanent when it persists for 3 months after anoxic brain injury

and 12 months after TBI.² Greater prognostic uncertainties exist for patients in a state of minimal consciousness, as these patients have consistent evidence of consciousness, awareness, and, in some, the ability to communicate. Because these patients have an unpredictable recovery, it is necessary to continue standardized assessment and therapy.

Physicians and care teams should utilize the latest medical evidence when discussing the probability of recovery from impaired consciousness with the family and surrogate decision maker. Further, it should be delineated that prognostication is inherently difficult. Outcome studies include a broader patient spectrum with a range of brain injury mechanisms. Furthermore, recovery is a dynamic and fluctuating process with marked individual variations. Such discussions require a delicate balance of perspectives on the need for clinical decision making and the inevitable fact of remaining medical uncertainties. Discussions with families and surrogates should include a thorough investigation about what the patient would have decided facing the inevitable scenario of permanent impaired (cognitive and physical) existence. This includes the importance of respecting a surrogate's decision that ongoing life support would have been unacceptable with the patient's wishes.

KEY POINTS

- Coma is a state of pathologic unresponsiveness from which the patient cannot be aroused. The eyes are closed, and only reflex responses or no responses at all can be elicited from the patient when applying vigorous stimulation.
- The cause of coma is diverse and follows neuronal injury, reversible or irreversible, to both cerebral hemispheres or to the reticular activating system in the diencephalon and brainstem.
- A supratentorial mass lesion located within one hemisphere can induce a lateral herniation syndrome with lateral torsion of the midbrain plus uncus herniation. In contrast a mass lesion located within the brain midline (i.e., acute hydrocephalus) primarily lead to downward herniation with rostral-caudal compression of the brainstem.
- An acute mass lesion below the tentorium (i.e., a cerebellar hemorrhage) early on compresses the brainstem, leading to cranial nerve deficits, obstructed CSF outflow resulting in hydrocephalus, and, if large enough, herniation of brain tissue upward through the tentorium and downward through the foramen magnum. On examination these patients may present with a complete lack of all cranial nerve and motor function, yet hemispheric function may be preserved.
- Initial attention must focus on the restoration of respiratory, hemodynamic, and metabolic homeostasis in parallel with a search to identify the cause and acuity of the coma state. Generally, a comatose patient's recovery depends on appropriate treatment of the underlying disorder but also very much on

KEY POINTS (Continued)

- monitoring and stabilizing brain function (ICP, perfusion, etc.).
- Status epilepticus is characterized by either clinically detectable (convulsive) or EEG-identified (nonconvulsive) seizure activity. Both require immediate and aggressive treatment to avoid permanent brain damage.
 - Alteration in cognitive function (especially attention and concentration deficit) is the earliest manifestation of metabolic encephalopathy. Some disease processes may provide specific diagnostic clues.
 - The neurologic examination consists of an assessment of the level of arousal determined by eye opening, verbal responses, and reflex or purposeful movements in response to noxious stimulation of the face, arms, and legs. Neuro-ophthalmologic function is evaluated by spontaneous eye movements, pupillary size and response to light, oculocephalic responses (doll's eyes), and oculovestibular (ice water caloric) responses. Autonomic function is assessed by the respiratory pattern and observing the monitored vital sign changes before and during examination.

CONCLUSIONS

The clinical examination in brain death is the most unequivocal in neurology. Most of the time, establishing the diagnosis of brain death on clinical grounds is not a difficult task, as long as providers follow established protocols and guidelines for the interpretation of findings during clinical examination.^{1,2} However, there may be confusion based on the variability of the interpretation of current guidelines,^{3,4} hurdles to clinical examination in specific patient populations such as trauma victims, laws from specific jurisdictions, and the changing face of outcomes after severe brain injury in an era of advancements in critical care and resuscitative medicine. In this chapter we will review current procedures and recommendations for the evaluation of comatose patients presumed brain dead, the concept of brain death substantiated by anatomic and physiologic bases, important concepts for the determination of brain death in the setting of novel interventions such as hypothermia and extracorporeal circulation, and how to avoid pitfalls during the evaluation of patients presumed brain dead.

HISTORICAL PERSPECTIVE AND DEFINITIONS

The concept of brain death is modern to medicine but the definition of death has historically been associated with physiologic cessation of cardiopulmonary function. With advancements in mechanical ventilation, life support, and resuscitation medicine, a new state in which a patient's cardiopulmonary functions could be sustained in the absence of neurologic function emerged. In 1959, Mollaret and Goulon described 23 patients with irreversible coma, whose clinical syndrome was characterized by the absence of brainstem function, spontaneous respiratory function,

and cardiovascular collapse that ensued without the use of vasopressors, in what became the birth of the concept of brain death.⁵ In 1963, Harvard neurologists proposed that a patient be certified as dead in the setting of coma, absence of brainstem reflexes, apnea for 30 minutes, and an isoelectric electroencephalogram (EEG) tracing in all leads for more than 30 minutes,⁶ despite the presence of cardiac function. The first guideline (the Harvard criteria) for deciding brain death was established in 1968.⁷ This concept has been accepted worldwide, although its fundamental meaning is not exactly globally uniform yet. Some countries, such as the United States, accept the concept of brain death as "whole brain death," which is defined as irreversible loss of all cortical and brainstem function. The Medical Royal Colleges of the United Kingdom established the definition of brain death on a "lower brain" concept of brainstem death.⁸ In the opinion of the Royal Medical College, permanent unconsciousness secondary to neuronal death of brainstem structures such as the reticular activating system (RAS) is irreversible.⁸

In 1981, a Presidential Commission in the United States was formed to address the issue of death by neurologic criteria.⁹ The President's Commission established the foundations of the criteria currently used in the United States for the diagnosis of brain death: the cause of brain death should be known and irreversible and no improvement in neurologic condition should occur during a period of observation; the period of observation was left at the discretion of the physician, but periods of 6 to 12 hours were recommended depending on the availability of confirmatory testing such as EEG or cerebral perfusion scans.⁹ Though the President's Commission suggested periods of observation of 24 hours for cases of ischemia-anoxia,⁹ more recent clinical experience in the era of therapeutic

hypothermia and published guidelines suggest a period of observation of up to 72 hours in patients with hypoxic-ischemic coma.¹⁰ The President's Commission guidelines for the determination of brain death culminated in a proposal for a legal definition that led to the Uniform Determination of Death Act (UDDA) in 1981. Under the law, the determination of death must be made with accepted medical standards and can be established only if an individual "has sustained either: 1) irreversible cessation of circulatory and respiratory functions, or 2) irreversible cessation of all functions of the entire brain, including the brain stem."

In 1995, the American Academy of Neurology (AAN) published the practice parameter to delineate the medical standards for the determination of brain death.¹¹ The guideline emphasized the three clinical findings necessary to confirm irreversible cessation of all brain functions including the brainstem: (1) known cause and presence of coma, (2) absence of brainstem reflexes, and (3) apnea.¹¹ Despite this publication, there is considerable practice variation in the adherence to the AAN guidelines for the determination of brain death, particularly in areas related to definitions of acceptable core temperature, number of required examinations, ancillary testing to be used,³ and deficiencies in documentation.³ In response to this phenomenon, the AAN published an evidence-based update of the 1995 Practice Parameter¹² to answer the main questions related to practice variability in the determination of brain death.^{3,13}

In the United States, most state laws have adopted the UDDA, and some have added their own amendments. All states and the District of Columbia have statutes for determining brain death based on the UDDA, but certain statutes differ in minor points such as the requirement that determination of brain death should be done by two different physicians, the use of confirmatory testing, and the notification of next of kin before the declaration of brain death. To this end, it is important for the practitioner to understand local hospital policies for the declaration of brain death that should abide by the laws of their respective jurisdictions. Additional information about specific status in jurisdictions of the United States can be downloaded from <http://www.braindeath.org>.

DETERMINATION OF BRAIN DEATH

The most common causes of brain death in the adult population are traumatic brain injury (TBI), aneurysmal subarachnoid hemorrhage (SAH), hypoxic-ischemic injury, and fulminant hepatic failure.¹⁴ It is estimated that the diagnosis of brain death is made at least 25 to 30 times a year in large referral centers, but this number may be lower in nonacademic centers.¹⁴ The determination of brain death is based on the UDDA and supported by the AAN Practice Parameter.^{11,12} The diagnosis is based on the establishment of three main criteria: (1) known cause and presence of coma, (2) absence of brainstem reflexes, and (3) apnea. Therefore, the clinical diagnosis, when considering accepted guidelines, is the most unequivocal in neurology.

In general, most jurisdictions require that the determination of brain death be made by a licensed physician, which in most of the cases should be an attending physician who has experience in the assessment of comatose patients and

the legal requirements applicable to the jurisdiction of practice. Some centers require the testing to be performed by two different physicians, and some centers require one of these physicians to be a neurologist, neurosurgeon, or critical care specialist. In the United States, 42% of top neuroscience centers required the brain death examination to be documented by a neurologist or neurosurgeon and only 35% required that an attending neurologist or neurosurgeon be involved; of the 42% centers, residents could document the examination in up to 65% of the centers.³ In those circumstances in which the patient is a potential organ donor, the clinical team may not be directly involved with the discussions of organ procurement, as a conflict of interest may be apparent.

CLINICAL EVALUATION OF COMA AND PREREQUISITES

Practitioners should first determine the cause of coma by history, physical examination, neuroimaging, and laboratory testing. Exclusion of central nervous system (CNS) depressants should be attempted by careful history taking, drug screen testing, and calculation of drug clearance using the rule of five times the drugs half-life (assuming a normal hepatic and renal function) or drug plasma levels below therapeutic ranges.¹² In the setting of abnormal hepatic or renal function, or after use of therapeutic hypothermia, caution should be taken before entertaining the diagnosis of brain death based on changes in drug metabolism inherent to these clinical settings, and to avoid catastrophic and embarrassing misdiagnoses.¹⁵ In these circumstances, more than recommended times for observation are suggested or the use of confirmatory testing may be sought. The legal limit for ethanol is a blood alcohol content of 0.08%, which is a practical threshold below which an examination to determine brain death could reasonably proceed.¹² In those patients exposed to pentobarbital for the management of intracranial hypertension, an accepted level in which a clinical examination can proceed without chance of confounding is 10 µg/mL.¹² There should be no temporal administration of neuromuscular blockers and this can be assessed definitely by the presence of train-of-four twitches with maximal ulnar stimulation. Acid-base status and electrolyte levels must not be severely deviated from the norm, but the presence of signs and symptoms of *diabetes insipidus* does not preclude the diagnosis of brain death; however, treatment with fluids and vasopressors such as vasopressin will target both sodium and blood pressure requirements to allow for adequate neurologic assessment. With more cardiac arrest survivors being exposed to therapeutic hypothermia, practitioners should now achieve a normal core temperature, defined as near-normal temperature or core temperature higher than 36° C, before attempting to determine brain death. Patients should have normal blood pressure, defined as systolic blood pressure (SBP) equal to or higher than 100 mm Hg, as the neurologic examination is usually reliable at this level of blood pressure.

A temporal cause of severe brain injury must be established. Irreversibility from neurologic injury is recognized by the extent of the injury, the devastation in neurologic findings, and the lack of improvement. Neuroimaging is useful in establishing an acute neurologic catastrophe that

Figure 62.1 Computed tomography scan of a young patient with traumatic brain injury showing right frontal contusion, mild subarachnoid hemorrhage, and severe cerebral edema. The patient has suffered bilateral transtentorial uncus herniations (*double arrow*, for right-sided uncus); note that the horn of the right lateral ventricle has been pushed toward the midline. The perimesencephalic cisterns are effaced (*single arrow*). There is slight hypodensity in the midbrain suggesting edema or ischemia.

is compatible with the clinical diagnosis. In most cases, a computed tomography (CT) scan will reveal specific findings such as diffuse cerebral edema, mass lesions with severe shift of midline structures, and herniation (Fig. 62.1).

Coma is established by the lack of all evidence of responsiveness. That is, eye opening or eye movement to noxious stimuli must be absent. The motor responses to noxious stimuli should not be flexor or extensor but spinally mediated. The clinical differentiation of motor responses may require experience and specific training in neurology or neurosurgery. When flexor posturing of the upper extremities and extension of the lower extremities (decorticate) or extensor posturing of both the upper and lower extremities (decerebrate) is observed, the diagnosis of brain death cannot be entertained and an additional period of observation is recommended (Fig. 62.2). The basis of these responses is related to the patency of the rubrospinal and vestibulospinal tracts, and lower segments of the medulla that connect with the spinal cord.¹⁶ Brain death patients typically exhibit spinal cord-mediated motor responses characterized by “en bloc” flexor responses of the lower extremities with flexion of the hip, flexion of the knee, and dorsiflexion of the ankle and toes (the so-called triple flexion response or Babinski en bloc spinal cord sign) (see Fig. 62.2). More complex movements that have been referred to as brain death-associated reflexes (Lazarus sign, spinal man, spinal reflexes, or spinal automatisms) have been described in patients who otherwise meet all other brain death criteria.¹⁷ When in doubt, the neurologic

examination of a comatose patient becomes equivocal, and in these circumstances, additional observation or a confirmatory test may be warranted.

ABSENCE OF BRAINSTEM REFLEXES

All segments of the brainstem should be tested in the clinical examination. The highest segments are examined by documentation of the pupillary response to bright light in both eyes (cranial nerves II and III). The usual presentation is dilated fixed pupils, which may be asymmetrical. Constricted pupils may mean drug intoxication or lesions at the level of the pons causing de-efferentation from sympathetic fibers and unopposed activation of parasympathetic centers located in the rostral area of the midbrain (Edinger-Westphal nucleus). Absence of ocular movements using oculocephalic and oculovestibular reflex testing can be achieved after assuring integrity of the cervical spine (cranial nerves III, IV, VI, and VIII [vestibular part]). The oculocephalic reflex is tested by briskly rotating the head side to side and vertically. Vertical oculocephalic movements are important for the determination of brain death as injuries in the lateral portions of the pons may manifest with bilateral palsies of horizontal eye movements but would spare the vertical eye movements. The oculovestibular or cold-caloric reflex is tested by irrigating each ear with 50 mL of iced water and observing the response for up to 1 minute. The absence of corneal reflexes (cranial nerves VII, V, and others) is demonstrated by touching the cornea with a cotton swab or gauze. Painful noxious stimulation in the cranium, trunk, or limbs should not produce any facial movement or grimacing (cranial nerve VII). Absence of pharyngeal (cranial nerve IX) or gag reflex (cranial nerve IX) is demonstrated by stimulating the back of the mouth or oropharynx with a suction device or tongue blade. The tracheal reflex (cranial nerve X) is tested by examining the cough response to tracheal stimulation provided by suctioning. Additional cranial nerve reflexes such as the “jaw jerk” (cranial nerve V) may be assessed for completeness and to follow established guidelines.¹¹ Any unanticipated movements of any segment of the face, trunk, or limbs during brainstem examination implies intact brainstem efferent connections and precludes the diagnosis of brain death. In trauma victims with facial trauma in whom adequate examination of brainstem patency cannot be substantiated, the use of confirmatory testing may be warranted.

Deviations from accepted guidelines during clinical examination of comatose patients presumed brain dead may be associated with false-positive results, so a thorough examination of all segments of the brainstem is required. Areas of particular deviation from the AAN Practice Parameter for the determination of brain death include failure of testing for pain above the foramen magnum, the oculocephalic reflex, the jaw-jerk reflex, and establishing the absence of spontaneous respirations³ (Fig. 62.3).

APNEA

Complete absence of breathing drive must exist to confirm the diagnosis of brain death. The absence of respiratory drive is tested with a CO₂ challenge, which requires all of the following: (1) normotension, (2) normothermia, (3)

Figure 62.2 The motor response to painful stimulation during the examination of comatose patients. **A**, Localization with right upper extremity and dorsiflexion of ankle and toe. **B**, Flexor posturing of the upper extremities and extension of the lower extremities (decorticate rigidity). **C**, Extensor posturing of both the upper and lower extremities (decerebrate rigidity). Note that the response of the lower extremities is always extensor in both flexor and extensor posturing. (From Saper CB: Brain stem modulation of sensation, movement, and consciousness. In Kandel ER, Schwartz JH, Jessell TM (eds): *Principles of Neural Science*. New York, McGraw-Hill, 2000, pp 889-909. Used with permission from McGraw-Hill.)

euvolemia, (4) eucapnia (P_{aCO_2} 35-45 mm Hg), (5) absence of hypoxia, and (6) no prior evidence of CO_2 retention (chronic obstructive pulmonary disease [COPD], severe obesity, or sleep apnea syndrome).¹² The test is started by preoxygenating the patient with 1.0 F_{IO_2} for 10 minutes to achieve a P_{aO_2} of more than 200 mm Hg using a respiratory rate of 10 per minute to achieve eucapnia. If the patient remains hemodynamically stable and with oxygen saturation more than 95%, the patient is disconnected from the ventilator and oxygenation is preserved by placing a catheter through the endotracheal tube and close to the level of the carina delivering O_2 at 1.0 F_{IO_2} with a flow of 6 L/minute. During the following 8 to 10 minutes, the practitioner should look carefully for respiratory movements (abdominal or chest excursions and may include a brief gasp).¹² The test should be aborted if oxygen saturation drifts lower than 85% for more than 30 seconds. If this is the case, the test can be repeated later using a T-piece, continuous positive airway pressure (CPAP) with 10 cm H_2O , and O_2 with 1.0 F_{IO_2} with a flow of 12 L/minute.^{12,18} The test is considered positive if respiratory movements are absent and the P_{aCO_2} is higher than 60 mm Hg or 20 mm Hg change from baseline supporting the diagnosis of brain death.¹²

Pitfalls in the diagnosis of brain death may be related to circumstances involving interference with the appropriate clinical diagnosis of brain death such as patients with (1) facial trauma (inability to appropriately examine cranial nerve responses or to elicit sensory/motor responses from stimulation above the level of the foramen magnum), (2) preexisting pupillary abnormalities, (3) toxic levels of anesthetics, sedatives, tricyclic antidepressants, anticholinergics, antiepileptics, or neuromuscular blocking agents, and (4) severe chronic respiratory acidosis (COPD, severe obesity, or sleep apnea syndrome). In these circumstances, a confirmatory test may be warranted.

CONFIRMATORY TESTING

The role of confirmatory testing in brain death differs among jurisdictions.¹⁹ In the United States and the United Kingdom, they are discretionary.^{11,12,20} According to the AAN guidelines, confirmatory tests are required only when specific components of the clinical examination cannot be reliably assessed.^{11,12} In some European countries such as Italy, France, and the Netherlands, among others, these tests

Figure 62.3 Variability during clinical examination of brain dead patients in top neuroscience centers of the United States. Poor compliance occurred mainly during testing of pain above the foramen magnum and the jaw jerk, as well as documenting absence of spontaneous respirations in brain death examination. OCR, oculocephalic reflex; OVR, oculovestibular reflex. Used with permission from Lippincott Williams & Wilkins.)

are mandatory,^{19,20} however, there is still significant variability in the approach to determining brain death in the world.¹⁹

A specialist in the neurosciences and any other skilled physician should be able to determine brain death using clinical criteria alone, so the main purpose of confirmatory testing besides being a diagnostic safeguard is to support the diagnosis of brain death in the setting of failure to complete a thorough neurologic examination or an apnea test. The important thing about confirmatory testing is that these tests should never replace the clinical examination and should never be ordered before attempts to complete a thorough neurologic examination.²¹

ORIGINS OF CONFIRMATORY TESTING IN BRAIN DEATH

In the earlier years of refining the clinical picture of brain death, there was a desire to demonstrate absence of brain function with information different from clinical data. In the 1950s Jouvet²² in France and C. Miller Fisher²³ in the United States began to use electrocerebral science to study a group of patients who would have poor neurologic outcomes. Although these studies provided the basis for defining brain death by the Ad Hoc Committee of the Harvard Medical School⁷ a year later, Beecher, who served as the chairman of the committee, mentioned in an editorial that

Table 62.1 Historical Time Frame for Confirmatory Tests Used in Determination of Brain Death

Year	Reported Study*	Test
1959	Löfstedt and von Reis ³⁹	Cerebral angiogram
1959	Fischgold and Mathis ⁴⁰	EEG
1969	Goodman et al ⁴¹	Nuclear brain scan

EEG was “not essential to a diagnosis of reversible coma, but provides valuable supporting data”²⁴ and this statement was later endorsed by the American Neurological Association.²⁵ Additional confirmatory tests, which can be divided into those that test for electrical function and those that test for blood flow, have been introduced and are aimed at confirming cerebral death (Table 62.1). Electrophysiologic tests include EEG, brainstem auditory evoked potentials (BAERs), and somatosensory evoked potentials (SSEPs); blood flow tests include four-vessel cerebral angiography, transcranial Doppler (TCD), CT angiogram, magnetic resonance (MR) angiogram, and nuclear brain scan (Fig. 62.4). More recent ancillary tests used for the determination of brain death include the bispectral index scale monitor²⁶ (BIS, mathematical algorithm of EEG), jugular bulb venous oxygen saturation (Sjvo₂),²⁷ and brain tissue oxygenation (PbtO₂).²⁸

ACCURACY OF CONFIRMATORY TESTS

Practitioners must be careful at the time of interpreting the results of confirmatory tests and be knowledgeable of the technology being used, as there are disparities in the accuracy of confirmatory tests that could lead to potential pitfalls in the determination of brain death (Box 62.1). Based on the absence of gold standards from a physiologic and pathologic perspective,²⁹ the results of confirmatory testing may confound the practitioner in two ways: tests can be labeled as false positives or false negatives when they are compared against each other. False positives occur when the test suggests brain death and the patient does not meet clinical criteria. False negatives are more common (Table 62.2), and they occur when the patient is clinically brain dead but the test shows otherwise,²¹ which may be more common with EEG.³⁰

Table 62.2 False-Negative Rates with Confirmatory Tests Used in Determination of Brain Death

Reported Study*	No. of Patients	Test†	False-Negative Rate
Petty et al, 1990 ⁴⁸	23	TCD	10% (2 patients)
Flowers and Patel, 1997 ⁴⁹	219	Nuclear brain scan	3% (6 patients)
Munari et al, 2005 ⁵⁰	20	Nuclear brain scan	5% (1 patient)

RECOMMENDATIONS FOR CONFIRMATORY TESTING

Current evidence-based guidelines from the AAN recommend the use of only one confirmatory test for the determination of brain death in those cases in which an additional period of observation, or an apnea test, or clinical examination is not feasible to fully establish the clinical criteria of brain death.¹² In a large study of brain death determination at the Mayo Clinic, the apnea test was aborted in 3% of patients and in 7% of patients the apnea test was not performed as it was not deemed to be safe, a situation that occurred more frequently in patients with polytrauma or with chest trauma.³¹ In practice, practitioners should anticipate that 1 in 10 patients with devastating neurologic injury

Box 62.1 Potential Pitfalls with Confirmatory Tests Used in Determination of Brain Death

Cerebral angiogram

- Image variability with injection of arch or selective arteries
- Image variability with injection and/or push technique
- No guideline for interpretation, operator-dependent

TCD

- Technically difficult and skill-dependent
- Normal findings in anoxic-ischemic injury

EEG

- Artifacts in intensive care settings
- Information from mostly cortex

SSEP

- Absent in comatose patients without brain death

CT angiogram

- Interpretation difficulties
- Retained blood flow reported in 205 cases
- Possibility to miss flow states because of rapid acquisition of images
- Delayed flow in low flow states (e.g., shock, heart failure)

Nuclear brain scan

- Areas of perfusion in thalamus in patients with anoxic injury or skull defect

CT, computed tomography; EEG, electroencephalogram; SSEP, somatosensory evoked potential; TCD, transcranial Doppler.

Adapted from Wijdicks EF: The case against confirmatory tests for determining brain death in adults. *Neurology* 2010;75:77-83; used with permission from Lippincott Williams & Wilkins.

will be unable to have an apnea test, and declaration of brain death may not be possible on clinical grounds. Families should be informed about the unlikely event of meaningful recovery and in these circumstances, if the patient is a candidate for organ donation, donation after circulatory determination of death (DCDD) may be considered; most hospitals have protocols for donation under DCDD,²¹ and this approach could potentially increase the supply of deceased donor organs.³²

SPECIAL CIRCUMSTANCES

DETERMINATION OF BRAIN DEATH AFTER CARDIAC ARREST IN THE ERA OF THERAPEUTIC HYPOTHERMIA

About 450,000 Americans have cardiac arrest annually.³³ The face of prognostication after cardiac arrest has changed in recent years based on clinical trials suggesting a robust effect of therapeutic hypothermia on clinical outcomes.³⁴ In 2006, the AAN published an algorithm to facilitate prognostic determination in patients who are resuscitated within 24 hours after cardiac arrest¹⁰ (Fig. 62.5). The algorithm may require modification as more information accrues on the effects of hypothermia and with validation of other tests for poor and favorable outcomes³⁵ but the most important feature of the new clinical practice parameter was the recommendation to practitioners to wait at least 24 hours before entertaining the diagnosis of brain death. Despite the practice parameter a recent study shows that prognostication after cardiac arrest occurs on the basis of insufficient clinical data, which may lead to early withdrawals on the basis of self-fulfilling prophecies of doom.³⁶

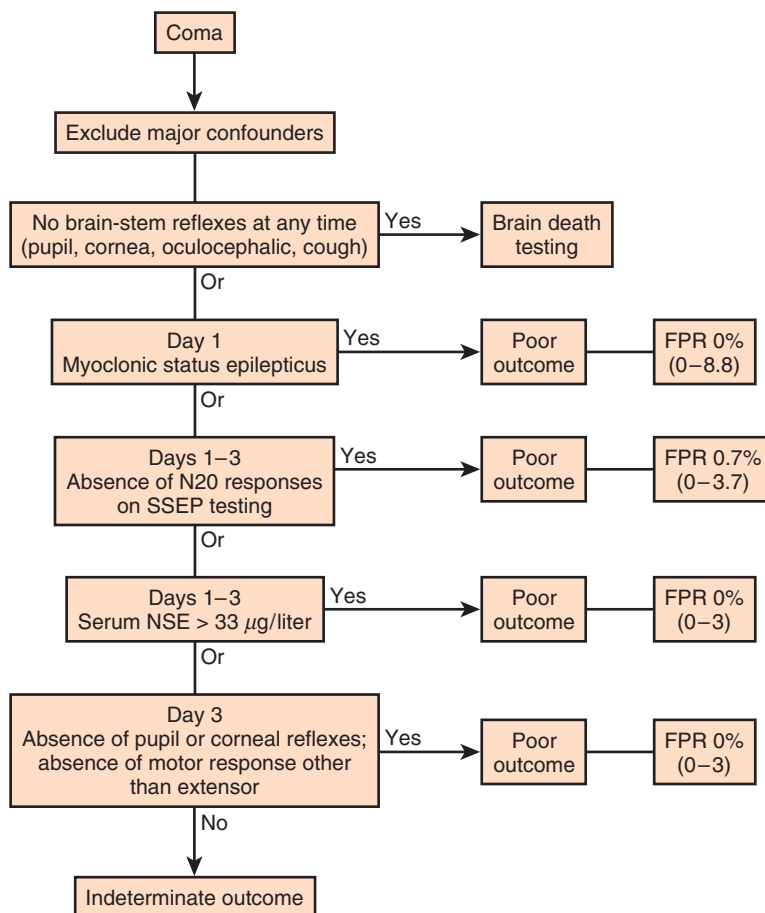

Figure 62.5 Decision algorithm for use in outcome prediction for comatose survivors of cardiac arrest. (From Wijdicks EF, Hijdra A, Young GB, et al: Practice parameter: Prediction of outcome in comatose survivors after cardiopulmonary resuscitation (an evidence-based review): Report of the Quality Standards Subcommittee of the American Academy of Neurology. *Neurology* 2006;67:203-210. Used with permission from Lippincott Williams & Wilkins.)

EXTRACORPOREAL MEMBRANE OXYGENATION

Extracorporeal membrane oxygenation (ECMO) is increasingly used as a means of extracirculatory support to patients in severe, reversible cardiac or respiratory failure. Patients presumed to have brain death may have earlier withdrawal of ECMO support,³⁷ which would limit the possibility of organ donation in patients who would otherwise be declared brain dead. In these circumstances, confirmatory testing may be warranted. A protocol of apnea testing involving the addition of CO₂ to the oxygenator to a target of 60 mm Hg or more than 20 mm Hg from the baseline normal CO₂ value may be used in lieu of the conventional protocol for apnea testing, but this protocol requires future validation.³⁸

CONCLUSIONS

In the United States, current legislation allows physicians to determine death on the basis of neurologic criteria. The diagnosis of brain death on clinical grounds is not a difficult task, as long as providers follow established protocols and guidelines for the interpretation of findings during the

clinical examination. The establishment of a known cause and presence of coma, the absence of brainstem reflexes, and apnea supports the diagnosis of brain death. Most jurisdictions require that the determination of brain death be made by a licensed physician, which in most of the cases should be an attending physician who has experience in the assessment of comatose patients and the legal requirements applicable to the jurisdiction of practice. When in doubt, an additional period of observation or a confirmatory test should be done to support in the determination of brain death.

KEY POINTS

- The clinical examination of brain dead patients is the most unequivocal in neurology.
- The determination of brain death in a comatose patient with catastrophic neurologic injury requires several consecutive steps supported by well-established guidelines.
- When the clinical diagnosis is in doubt or interferences to obtain a thorough clinical examination are present, a confirmatory test may be used to determine brain death in adults.
- Confirmatory testing should not be used in lieu of clinical examination, and when indicated, only one confirmatory test should be performed.
- A period of observation of up to 24 hours after cardiac arrest in patients exposed to therapeutic hypothermia may be required before fully entertaining the determination of brain death.

SUMMARY

HISTORICAL BACKGROUND

Stroke has a major impact in the United States, with an estimated yearly incidence of 731,100 new and recurrent strokes¹ from 1993-1994. In 1997, 821,760 stroke admissions occurred in this country.² Stroke constitutes the third leading cause of death and is a major cause of disability.³ Although stroke is a lesser cause of disability than heart disease,⁴ the population of stroke survivors continues to increase, in part because of a fall in mortality rate.⁵ Historically, stroke was not emphasized in the critical care setting because of the limited scope of interventions in the past. In the early 1990s, neurologic diseases, including but not limited to stroke, accounted for a mere 6% to 7% of admissions to critical care units.⁶ Now there is acute treatment for stroke, namely, the use of tissue plasminogen activator (tPA) for ischemic stroke within 3 hours of symptom onset,⁷ as well as intra-arterial (IA) thrombolysis for as long as 6 hours following stroke onset.⁸ A clot removal device (mechanical embolus removal in cerebral ischemia, or MERCI)⁹ has been approved, and newer, likely more effective, devices¹⁰ may become available shortly. Thrombolytic agents designed to work within a 9-hour time window, in conjunction with sophisticated imaging, have been studied, although they have not yet been shown to be useful.¹¹ The great danger with the use of these agents is the risk of intracerebral hemorrhage (ICH). Frequent monitoring, as often as every 15 minutes following administration of a thrombolytic, is standard for patients so treated, and observation in a critical care unit is required.

Consequently, critical care physicians need to learn about this condition, which has become a regular part of their professional lives, particularly in centers that devote themselves to the care of stroke patients. In one critical care unit with which the author is familiar, ischemic stroke accounts for 3% of the primary admissions and hemorrhagic stroke for 5.4%.¹²

OVERVIEW

This chapter reviews the general diagnosis and treatment of ischemic stroke. It describes the following:

- The specific interventions available
- Their rationale and utility
- New developments in the area
- The reasons for critical care consultation

Stroke is traditionally defined as a focal neurologic deficit of presumed vascular onset, lasting 24 hours or longer, as opposed to transient ischemic attack (TIA), which is an episode shorter than 24 hours in duration.¹³ Many TIAs actually last for less than 60 minutes.¹⁴

Stroke symptoms, including retinal TIA (*amaurosis fugax*), arise either from the territory fed by the internal carotid artery or from the vertebrobasilar system. The carotid, through its major branches, the anterior cerebral arteries (ACAs) and middle cerebral arteries (MCAs), provides blood to the major portion of the cerebral hemispheres. The vertebrobasilar system, in contrast, perfuses the brainstem and cerebellum, as well as the inferior and medial aspects of the occipital and temporal lobes, and the thalamus.

Carotid symptoms, as listed in [Box 63.1](#), primarily consist of hemisensory loss, hemiparesis, and retinal ischemia (monocular blindness). Left hemispheric ischemia, generally in the perisylvian area, may result in varying degrees of aphasia.¹⁵ Involvement of the sensory association areas within the right parietal lobe can produce the phenomenon of neglect.¹⁶ In neglect, a stimulus is felt when it is alone but not in the presence of a competing stimulus. For example, a touch on the left hand or an object in the left visual field may be perceived when alone, but not when another stimulus is simultaneously presented, generally on the right side (double simultaneous stimulation). In that instance the

Box 63.1 Stroke Symptoms**Carotid Distribution**

1. Hemiparesis
2. Hemisensory loss
3. Aphasia
4. Retinal ischemia
5. Neglect
6. Homonymous hemianopia

Vertebrobasilar Distribution

1. Motor dysfunction—crossed or bilateral
2. Sensory loss—crossed or bilateral
3. Gait ataxia
4. Homonymous hemianopia
5. Diplopia, dysphagia, dysarthria, vertigo, hiccups—none of these alone qualify as stroke/transient ischemia attack symptoms
6. Combinations of the above

Symptoms Not Considered Vascular in Origin

1. Syncope or presyncope
2. Dizziness, “wooziness,” giddiness
3. Impaired vision associated with alteration of consciousness
4. Any of the following in isolation: amnesia, confusion, vertigo, diplopia, dysphagia, dysarthria
5. Tonic or clonic motor activity
6. March of sensory or motor deficits
7. Focal symptoms in association with migraine
8. Bowel or bladder incontinence

Modified from Hachinski V, Norris JW: *The Acute Stroke*. Philadelphia, FA Davis, 1985.

right-sided stimulus alone is perceived. In extreme circumstances, affected individuals may not recognize the left side of the body as being theirs (*anosognosia*), as described memorably by Oliver Sacks in *The Man Who Mistook His Wife for a Hat*.¹⁷

Box 63.1 lists symptoms resulting from ischemia in the vertebrobasilar territory, which includes the cerebellum, brainstem, and the medial aspect of the occipital lobe, as well as the thalamus and the inferomedial portions of the temporal lobe. As a result, vertebrobasilar ischemia can produce cranial nerve dysfunction, nystagmus, cerebellar dysmetria, ataxia, and long tract signs such as sensory loss or motor impairment. These may involve one or both sides of the body. Memory disorders and visual field deficits also occur. In extreme circumstances, when the basilar artery becomes occluded, coma or quadriplegia may develop, although the presentation may vary, as described by Kubik and Adams¹⁸ in 1946. As a result of coma or quadriplegia, mechanical ventilation may be required, and the prognosis in such patients is grim. In one study,¹⁹ 22 of 25 patients died, and the other 3 lingered in the “locked-in syndrome.”²⁰ This frightening manifestation of basilar occlusion, secondary to pontine infarction, leaves patients chronically limited to eye blinking as their sole means of communication.

Differentiating between carotid and vertebrobasilar symptoms is important. There exists intervention to repair carotid stenosis, which is most effective following stroke

Box 63.2 Common Seizure Symptoms

Tonic movements
Clonic movements
Jacksonian march (sensory, motor, or both)
Automatisms (grimacing, chewing)

or TIA in the distribution of the affected vessel. Failure to recognize symptoms as originating from the vertebrobasilar territory may lead to unwarranted intervention for carotid narrowing.

Likewise, one must not label complaints that are not cerebrovascular in nature as stroke (see Box 63.1). Syncope, wooziness, and the like usually reflect systemic hypotension as opposed to focal ischemia. The still widespread practice of studying carotid vessels—most often through ultrasound—following the development of syncope should be abandoned because syncope does not result from ischemic stroke.

In Box 63.1, item 4 under “Symptoms Not Considered Vascular in Origin” draws attention to the fact that certain symptoms may represent stroke when associated with other symptoms but not in isolation. Vertigo, for instance, can result from disease of the semicircular canals. If other complaints or findings referable to the posterior fossa of the brain (brainstem and cerebellum) coexist, such as those listed in Box 63.1 under “Vertebrobasilar Distribution,” the symptoms may indeed localize there. Similarly, amnesia alone may follow a seizure or result from transient global amnesia as opposed to stroke, and so on.

The items listed in Box 63.2 reflect the presence of seizures. Seizure onset may be unwitnessed, and in the hospital only postictal deficits, such as aphasia or hemiparesis, may be observed. The appearance of any number of positive phenomena will draw attention to the correct diagnosis. These phenomena contrast with the abolition of normal function that happens with stroke and instead represent abnormal activity resulting from uncontrolled electrical discharges. Occasionally, however, limb shaking may represent carotid ischemia, usually as the result of hemodynamic compromise in the territory of the ipsilateral carotid artery.²¹ Dreifuss²² gives a comprehensive classification of epilepsy types and symptoms.

Migraine can also be associated with focal neurologic complaints. Commonest among these are visual complaints including scotomas, whether scintillating or not. The most dramatic manifestation is hemiplegic migraine, which raises the fear of ICH at first presentation. Aphasia and paresthesia are also described. Silberstein and colleagues²³ have reviewed the manifestations of migraine.

Box 63.3 lists those entities that most frequently mimic stroke. Hypoglycemia may produce focal neurologic deficits. Occasionally a mass lesion such as tumor or subdural hematoma may present with fluctuating deficits or be revealed by seizure activity that may be confused with stroke. In the case of subdural hematoma in the elderly, the inciting trauma may have been minor or forgotten. Headache may be prominent, mild, or even absent. Mass lesions and hemorrhage are frequently marked by confusion, decreased

Tumor

level of consciousness, or headache, but if the lesion is small, these symptoms may not appear. Consequently, blood sugar measurements and computed tomography (CT) scans (without contrast) are obligatory in all instances of suspected stroke. Within the first 6 hours of the event, CT may well be negative, even in instances of major infarction such as that involving the entire MCA watershed. Thus CT finds its greatest utility not in confirming the clinical diagnosis but in excluding the presence of small hemorrhages. Neurologists have relied on clinical findings to diagnose stroke, especially in the hyperacute phase (0 to 6 hours), when CT is least helpful.

ADVANCES IN RADIOLOGY

With the advent of diffusion-weighted imaging (DWI), magnetic resonance imaging (MRI) scans (Fig. 63.1) can now be used to detect acute cerebral ischemia within the initial 6-hour period following symptom onset.²⁴ This allows the clinician to confirm or exclude the presence of stroke in doubtful cases. Most commonly, such circumstances involve the possibility of a new lesion in a previously injured area of the brain. For example, in the case of a new seizure originating from the hemisphere affected by a prior stroke, DWI can show whether the new event is seizure alone or caused by a new stroke. By the same token, if a newly delirious or febrile patient should manifest worsening of a preexisting neurologic deficit, DWI will clarify whether the worsening stems from the intercurrent injury or from a coincident new stroke. DWI can also reveal silent areas of cerebral ischemia, which sometimes appear simultaneously with the area of injury that presents symptomatically as stroke. The coincident development of ischemia in different vascular territories may indicate the presence of an unusual mechanism of infarction, such as vasculitis, hypercoagulable state, or cardiac source of emboli. MRI has been proved to be just as effective as CT in detecting ICH,²⁵ thus potentially removing an extra step (the initial head CT) from the stroke evaluation. Unfortunately, MRI is less immediately available than CT, requires more time and cooperation from the patient, and may not be feasible in the face of claustrophobia or of ferromagnetic implants/fragments within the body.

Both CT and MRI technology can delineate the cerebral vasculature in detail, starting from the aortic arch and extending to the vicinity of the circle of Willis. Computed tomographic angiography (CTA) has been shown to be reliable in studying the intracranial vasculature²⁶ and the extracranial segment of the carotid artery (Fig. 63.2).²⁷ Magnetic resonance angiography (MRA) is superior to ultrasound in detecting carotid artery stenosis in the neck²⁸ and is effective

Figure 63.1 Cerebral infarction as shown by diffusion-weighted imaging (arrow) on magnetic resonance imaging. Hyperdensity in the right middle cerebellar peduncle is demonstrated.

as well intracranially²⁹ (Figs. 63.3 and 63.4), although its specificity and sensitivity in both instances are likely to improve. CTA has its own limitations, namely, the difficulty in performing the study in patients with contrast dye allergies. Because of these new techniques, the performance of conventional cerebral angiography is limited to specific indications, as outlined in Box 63.4.

Figure 63.4 Shown are magnetic resonance angiography (*left*) and computed tomographic angiography (*right*) of the extracranial carotid artery in a patient with internal carotid artery stenosis (*arrows*) located above the common carotid bifurcation.

THROMBOLYSIS IN STROKE

The era of thrombolysis in acute stroke began with the publication of the NINDS (National Institute of Neurological Disorders and Stroke) tPA trial in 1995.⁷ This groundbreaking study was the first to demonstrate a beneficial

Box 63.4 Indications for Conventional Cerebral Angiography

- To ascertain the precise degree of arterial stenosis, most often of the extracranial carotid artery, in doubtful cases
- To detect and map intracranial aneurysms and arteriovenous malformations
- To determine patterns of collateral flow in the brain
- To diagnose vasculitis
- To detect intraluminal thrombus
- To enable intra-arterial thrombolysis or mechanical clot extraction
- For the performance of carotid angiography and stenting

effect of tPA when given to patients presenting within 3 hours of the onset of the event. Depending on the criteria used to determine favorable outcome at 3 months, roughly an additional 11% to 13% of subjects receiving tPA recovered with little or no disability. If one uses the National Institutes of Health stroke scale (NIHSS) (Table 63.1) score, a reliable measure³⁰ to measure disability, the improvement was from 20% with minimal or no disability with placebo to 31% with tPA. This was counterbalanced by an increase in the rate of ICH, from 0.6% in the placebo group to 6.4% in the tPA cohort. Half the subjects in the placebo group who suffered ICH died, whereas the mortality rate from ICH in the tPA cohort was 2.9% (less than half). Hemorrhage following tPA use occupies the same area of the brain affected by the initial thrombosis in most but not all cases.³¹

Strict inclusion (Box 63.5) and exclusion (Box 63.6) criteria are applied to attempt to minimize the risk of ICH. The safety and efficacy of thrombolysis have not been analyzed in children. The time of onset of symptoms is taken to be the last time that the patient was seen to be normal. For example, an individual who went to sleep at 10 PM and awoke at 6 AM, immediately hemiplegic, will not qualify for tPA therapy. One who awoke at 4 AM, went back to sleep, and awoke again at 6 AM with stroke symptoms may be treated with tPA, but only up to 7 AM. A person who awoke at 6 AM, was briefly normal, and developed stroke symptoms at 6:05 AM may be treated until 9:05 AM.

The blood glucose must be determined before initiating tPA therapy to avoid misdiagnosing hypoglycemia as stroke (see Box 63.3). A CT scan of the head is essential to look for a mass, most often an ICH or subdural hematoma. The CT must also be scrutinized for the presence of early ischemic changes, such as sulcal effacement, hypodensity within the brain, or loss of definition between structures within the

brain, or for the presence of a hyperdense MCA, suggestive of thrombosis.³² Whether ischemic changes on CT predict a heightened risk of hemorrhagic transformation is controversial.^{31,33} However, CT findings appear more commonly among subjects with scans performed relatively late in the course of their stroke.³³ Hence their appearance should prompt reevaluation of the time of onset of the stroke. Prior ICH, recent stroke, and hypertension at presentation are believed to increase the risk of sustaining ICH. Avoiding systemic bleeding, which may result in hypotension and worsening of the neurologic deficit, is also important. Extremes of blood glucose or the presence of a coincident

Box 63.6 Thrombolysis Exclusion Criteria at 0-3 Hours

Stroke or serious head injury within the past 3 months
 Major surgery within the previous 14 days
 Prior history of intracerebral hemorrhage
 Systolic blood pressure >185 mm Hg or diastolic blood pressure >110 mm Hg
 Rapid neurologic improvement or minor deficit
 Symptoms suggestive of subarachnoid hemorrhage
 Gastrointestinal or genitourinary hemorrhage within the previous 21 days
 Evidence of significant bleeding or fracture on examination
 Arterial puncture at a noncompressible site within the previous 7 days
 Seizure with postictal residual neurologic deficits
 Anticoagulation or heparin use within 48 hours before treatment and elevated PTT
 Prothrombin time greater than 15 seconds or INR greater than 1.7
 Platelet count less than 100,000/ μ L
 Blood glucose less than 50 mg/dL or greater than 400 mg/dL
 Recent use of low-molecular-weight heparin
 Large myocardial infarction in the past 3 months
 CT scan of the brain with hypodensity involving less than one third of the cerebral hemisphere
Caution should be exercised in treating:

- Patients with major deficits
- Patients who have undergone lumbar puncture or organ biopsy within the preceding 7 days
- Patients with hyperglycemia (>400 mg/dL)

CT, computed tomography; INR, international normalized ratio; PTT, partial thromboplastin time.

seizure make the neurologic deficit seem worse than it is, rendering calculation of a risk-benefit ratio more difficult.

Two blood tests must be checked before embarking on thrombolysis: a blood sugar, as mentioned earlier, and a platelet count. If the patient is on anticoagulant therapy, the prothrombin time/international normalized ratio or partial thromboplastin time must be available before deciding whether to proceed with treatment. If a patient is not known to be receiving anticoagulants at baseline, but the coagulation profile proves abnormal, the infusion must be stopped if thrombolysis is still ongoing at the time that the abnormal value returns. If a patient is receiving low-molecular-weight heparin, there is no rapid way of determining the degree of anticoagulation, and intervention must be withheld. Testing for the activity of factor Xa antagonists is not yet standardized, although a normal thrombin time may suggest that thrombolysis is safe.³⁴

If the blood pressure is elevated (>180 mm Hg systolic or 110 mm Hg diastolic), a modest dosage of labetalol, 5 to 10 mg IV (intravenous), may be given and repeated if necessary, up to a maximum dosage of 40 mg. Nitropaste is a less exact alternative but has the advantage that it can be removed. A nicardipine drip may be employed as well, which constitutes a change from prior guidelines. If the blood pressure subsequently rebounds to an undesirable range, tPA should not be given. If the pressure should rise

above 180 mm Hg systolic or 105 mm Hg diastolic subsequent to starting the tPA infusion, it is paramount to bring it down using IV infusions of antihypertensive agents (Table 63.2).³⁵ In this context, it is worth emphasizing that blood pressure should be treated acutely only when there exists a specific indication for doing so, as defined in the table.

tPA should not be given in the presence of a deficit mild enough that reasonable recovery may be expected within 3 months. However, there is not a clear cutoff based on the NIHSS to identify those patients whose deficits are too mild to warrant intervention. The choice falls to the treating

physician. For instance, a partial hemisensory loss, facial palsy, or mild dysarthria would not normally warrant treatment with tPA when appearing in isolation. A hemianopia in a bedridden elderly subject residing in a nursing facility may not be considered deserving of thrombolysis by some physicians. However, an active middle-aged person presenting with an isolated hemianopia would probably be treated more aggressively by most doctors. The most difficult choices exist in the setting of mild motor or speech deficits. Such deficits may recover well, but a percentage of subjects will worsen while in the hospital and then no longer be candidates for rescue using thrombolysis. Unfortunately, we

Table 63.2 Approach to Elevated Blood Pressure in Acute Ischemic Stroke

Blood Pressure Level (mm Hg)	Treatment
A. Not Eligible for Thrombolytic Therapy	
Systolic <220 mm Hg OR diastolic <120 mm Hg	Observe unless other end-organ involvement (e.g., aortic dissection, acute myocardial infarction, pulmonary edema, hypertensive encephalopathy) Treat other symptoms of stroke (e.g., headache, pain, agitation, nausea, vomiting) Treat other acute complications of stroke including hypoxia, increased intracranial pressure, seizures, and hypoglycemia
Systolic >220 mm Hg OR diastolic 121-140 mm Hg	Labetalol 10-20 mg IV over 1-2 min May repeat or double every 10 min (maximum dose 300 mg) OR Nicardipine 5 mg/hr IV infusion as initial dose; titrate to desired effect by increasing 2.5 mg/hr every 5 min to maximum of 15 mg/hr Aim for a 10-15% reduction in blood pressure
Diastolic >140 mm Hg	Nitroprusside 0.5 µg/kg/min IV infusion as initial dose with continuous blood pressure monitoring Aim for a 10-15% reduction in blood pressure
B. Eligible for Thrombolytic Therapy	
Pretreatment	
Systolic >185 mm Hg OR diastolic >110 mm Hg	Labetalol 10 to 20 mg IV over 1 to 2 min, may repeat _1; OR Nitropaste 1 to 2 inches OR Nicardipine infusion, 5 mg/hr, titrate up by 2.5 mg/hr at 5- to 15-min intervals, maximum dose 15 mg/hr; when desired blood pressure attained, reduce to 3 mg/hr If blood pressure does not decline and remains >185/110 mm Hg, do not administer rtPA
During/after Treatment	
1. Monitor blood pressure	Check blood pressure every 15 min for 2 hr, then every 30 min for 6 hr, and finally every hour for 16 hr
2. Diastolic >140 mm Hg	Sodium nitroprusside 0.5 µg/kg/min IV infusion as initial dose and titrate to desired blood pressure
3. Systolic >230 mm Hg OR diastolic 121-140 mm Hg	Labetalol 10 µg IV over 1-2 min May repeat or double labetalol every 10 min to maximum dose of 300 mg; or give initial labetalol dose, then start labetalol drip at 2-8 mg/min OR Nicardipine 5 mg/hr IV infusion as initial dose and titrate to desired effect by increasing 2.5 mg/hr every 5 min to maximum of 15 mg/hr; if blood pressure is not controlled by labetalol, consider sodium nitroprusside
4. Systolic 180-230 mm Hg OR diastolic 105-120 mm Hg	Labetalol 10 mg IV over 1-2 min May repeat or double labetalol every 10-20 min to maximum dose of 300 mg; or give initial labetalol dose, then start labetalol drip at 2-8 mg/min

rtPA, recombinant tissue plasminogen activator.

From Adams HP, del Zoppo G, Alberts MJ, et al: Guidelines for the early management of adults with ischemic stroke. *Stroke* 2007;38:1655-1711.

presently lack a tool to predict which subjects will worsen during their acute hospital stay.

Subjects who have been on antiplatelet agents such as aspirin before their event may receive tPA, but no anticoagulants or antiplatelet agents should be given for the 24 hours following the start of tPA therapy. Arterial punctures, nasogastric tubes, and catheterization should be avoided unless they are essential to care, in order to minimize the risk of bleeding.

Hypotension may develop, raising the concern of systemic hemorrhage. Of course, hypotension may have a variety of other causes. The most feared event following tPA use is the development of ICH. The presenting signs and symptoms appear in [Box 63.7](#). Most are self-explanatory. Hypertension is a compensatory response to increased intracranial pressure (ICP), to maintain cerebral perfusion, and bradycardia occurs secondary to it.

The steps to be taken with suspected ICH appear in [Box 63.8](#). It is relatively uncommon for neurosurgeons to intervene on hemorrhages in the setting of tPA because of the risk of further bleeding into the surgical bed. Systemic hemorrhage is handled in a similar fashion, but transfusion may also be necessary. Platelets should be administered if the count is significantly decreased ($<50,000$ cells/ μL).

The benefit of tPA is greatest in the instances of the smallest vascular occlusions (lacunar, as opposed to cortical, infarcts). Older subjects with particularly severe strokes are most likely to have a poor outcome, but even in this group tPA remains beneficial overall.³⁶ The sooner tPA is administered, the higher the likelihood of successful recovery, as shown by a meta-analysis³⁷ of thrombolysis trials. A residual

benefit of tPA exists, as far out as 6 hours from the ictus. Two studies^{38,39} that specifically examined treatment beyond 3 hours failed to show a benefit of administration of tPA within a 5- or 6-hour time frame. More recently, however, the ECASS-III (European Cooperative Acute Stroke Study III) trial⁴⁰ established the utility of tPA administration in the 3.0- to 4.5-hour period following stroke onset. The inclusion and exclusion criteria are more restrictive than those for treatment within 3.0 hours ([Boxes 63.9](#) and [63.10](#)). Initially, there was some concern about the administration of tPA within the 3.0- to 4.5-hour window to subjects with a history both of prior stroke and of diabetes. A statistical analysis⁴¹ based on datasets from large registries suggests that neither factor predisposes to poor outcome in reality. No doubt there exists a subgroup of subjects presenting beyond 4.5 hours that remains amenable to treatment, but this group cannot yet be identified.

Box 63.7 Signs and Symptoms of Intracerebral Hemorrhage

- Marked hypertension
- Bradycardia

Box 63.8 Management of Suspected Intracerebral Hemorrhage after Use of Tissue Plasminogen Activator (tPA)

- Discontinue the tPA infusion if it remains in progress.
- Obtain CT scan of the head (noncontrast) STAT.
- Order PT, PTT, platelet count, fibrinogen level STAT.
- Type and crossmatch blood.
- Arrange for neurosurgery consultation.
- Administer fresh frozen plasma or cryoprecipitate (4 to 8 units).

CT, computed tomography; PT, prothrombin time; PTT, partial thromboplastin time.

Box 63.9 Thrombolysis Inclusion Criteria at 3.0-4.5 Hours

- Age 18 to 80 years
- Onset of stroke symptoms 3.0 to 4.5 hours before initiation of study drug
- Stroke symptoms present for at least 30 minutes with no significant improvement before treatment

Box 63.10 Thrombolysis Exclusion Criteria at 3.0-4.5 Hours

- Intracranial hemorrhage
- Time of symptom onset unknown
- Symptoms rapidly subsiding or only minor before start of infusion
- Severe stroke as assessed clinically (e.g., NIHSS score >25) or by appropriate imaging techniques*
- Seizure at onset of stroke
- Stroke or serious head trauma within previous 3 months
- Administration of heparin within 48 hours preceding onset of stroke, with an activated partial thromboplastin time at presentation exceeding the upper limit of the normal range
- Platelet count of less than $100,000/\mu\text{L}$
- Systolic pressure greater than 185 mm Hg or diastolic pressure greater than 110 mm Hg, or aggressive treatment (intravenous medication) necessary to reduce blood pressure to these limits
- Blood glucose less than 50 mg/dL or greater than 400 mg/dL
- Symptoms suggestive of subarachnoid hemorrhage, even if CT scan was normal in appearance
- Oral anticoagulant treatment
- Major surgery or severe trauma within previous 3 months
- Other major disorders associated with an increased risk of bleeding

*A severe stroke as assessed by imaging was defined as a stroke involving more than one third of the middle cerebral artery territory. On the NIHSS, total scores range from 0 to 42, with higher values reflecting more severe cerebral infarcts.

CT, computed tomography; NIHSS, National Institutes of Health Stroke Scale.

Various authors have identified different predictors of ICH following treatment with tPA. Levy and colleagues⁴² identified the dosage of tPA given, the age of the subjects, and diastolic hypertension as pertinent factors. Larrue and colleagues³¹ also found age to heighten the risk of development of ICH, but not the degree of hypertension or the time to treatment. It has become clear that tPA can be given safely in the community⁴³ and that complication rates of tPA use can be lowered to a satisfactory level by careful adherence to the exclusion criteria.⁴⁴

IA thrombolysis can be used to treat acute ischemic stroke beyond the 3-hour time window for IV tPA. Basilar thrombolysis has been treated as late as 24 hours after the onset of symptoms using this approach.⁴⁵ Other subjects with occlusion of the proximal (M1 or M2) segments of the MCA have been successfully treated between 3 and 6 hours following stroke onset. The utility of this approach rests on the PROACT II (Prolyse in Acute Cerebral Thromboembolism II) trial,⁸ a study using a novel agent, prourokinase (pro-UK). In contrast to the IV tPA trial, aspirin was allowed in the first 24 hours following stroke onset and heparin was used acutely following pro-UK to prevent vascular occlusion. To enter the study, the upper age limit was 85 years and the minimum NIHSS score was 11.

The trial showed a 40% rate of favorable neurologic outcome at 3 months following IA thrombolysis, as opposed to 25% in the control group. The rate of ICH with clinical deterioration at 24 hours following study entry was 10% in the pro-UK group, as opposed to 2% in the placebo group. Although pro-UK itself has not been approved for use in this country, IA tPA is used for subjects who cannot be treated within 3 hours with IV tPA, and, despite the absence of studies, as rescue therapy following IV tPA use. The inclusion and exclusion criteria are similar to those for IV tPA. The availability of mechanical clot extraction, as summarized later, means that subjects who do not qualify for IA tPA may still receive treatment, again in the absence of definitive trials. Apparent predictors of hemorrhagic transformation of cerebral infarct in patients subjected to IA thrombolysis appear in Box 63.11.⁴⁶ In another study,⁴⁷ 36 subjects underwent IA thrombolysis for stroke within 2 weeks of major surgery (mean time from surgery to treatment of 21.5 hours). Nine of the subjects (25%) died, but only three died of hemorrhagic complications, suggesting that IA thrombolysis may be considered following major surgery when IV thrombolysis is contraindicated. The smaller dosage of thrombolytic (0.2 mg/kg vs. 0.9 mg/kg)

used may render the IA approach safe in this setting. IA thrombolysis is also used when cardiac catheterization is complicated by stroke, in large part because of immediate access to the vascular tree. This approach, although reasonable, has not been studied systematically.⁴⁸

The use of a 0.6-mg/kg systemic bolus of IV tPA acutely, followed by IA thrombolysis if shown necessary by immediate angiography, was examined by the IMS (Interventional Management of Stroke) II trial.⁴⁹ A microcatheter was employed, when feasible, to allow for ultrasound-assisted clot lysis in addition to local instillation of tPA. There were trends toward higher incidence of ICH, but better clinical outcomes overall, when compared to the original NINDS tPA trial. The IMS III trial,⁵⁰ a randomized comparison of IV tPA against IV/IA therapy, the latter enhanced by mechanical clot extraction, has begun.

Neurointerventionalists attempt to heighten the effectiveness of local thrombolytics by using catheters to mechanically disrupt clots. Such an approach is difficult to assess in a standardized fashion. There exist data on the MERCI device, designed to extract clot via the endovascular approach without thrombolysis. Initially, this approach was tested in subjects ineligible for tPA,⁹ but it has also been tested subsequently in subjects previously treated with IV tPA.⁵¹ Even though a trend toward increased ICH emerged, vessel recanalization rates were relatively high, approaching 70% in patients also treated with IA tPA. This intervention was used, when needed, to dissolve clot resistant to device intervention or to treat inaccessible distal thrombus. A newer and possibly more effective device, Solitaire,¹⁰ may shortly be available.

Such devices have been compared to each other, but not to placebo. Available data consist of series of patients treated with a device compared with historical control subjects. The data focus on the rate of recanalization of the occluded vessel and only secondarily on clinical outcome. The limitations of such an analysis are discussed in detail elsewhere.⁵² Mechanical clot extraction will find a role in the acute treatment of ischemic stroke, which remains to be defined.

Radiologic imaging has been proposed as a tool to determine when individual subjects may be suitable for IA intervention, regardless of time from stroke onset. Specific patients may, by virtue of good collateral flow, possess a significant area of ischemic but viable brain that may be salvaged by endovascular treatment, even if beyond standard time windows. This algorithm may apply particularly to “wake-up” strokes. Computed perfusion tomography (CT perfusion) can be used to estimate the size of the ischemic area but not infarcted area at presentation,⁵³ and diffusion-weighted/perfusion-weighted MRI may identify those patients who will benefit from intervention.⁵⁴ However, these tools need validation and standardization in large studies in order to attain clinical efficacy.

Box 63.11 Predictors of Hemorrhagic Transformation of Cerebral Infarction after Intra-arterial tPA

- Higher NIHSS score
- Longer time to arterial recanalization
- Hyperglycemia
- Lower platelet count

NIHSS, National Institutes of Health Stroke Scale; tPA, tissue plasminogen activator.

SYMPTOMATIC CAROTID DISEASE/STENTING

Carotid endarterectomy (CEA) dramatically reduces stroke risk in patients with cerebral or retinal ischemia who prove to harbor a significant carotid stenosis ipsilateral to the affected cerebral hemisphere. Two separate randomized

controlled trials^{55,56} have shown similar results. In NASCET (North American Symptomatic Carotid Endarterectomy Trial),⁵⁶ the risk of stroke fell from 26% over 2 years in the nonsurgical group to 9% over 2 years in the surgical group, with a surgical morbidity and mortality rate of 5.6%. The patients had stenosis of 70% or greater. A more modest benefit was seen in men with stenoses between 50% and 69%; namely, they showed a reduction in stroke risk from 22.2% over 5 years without surgery to 14.9% over 5 years with surgery. This is an absolute reduction of the stroke rate of 7.3% over 5 years, as opposed to an absolute reduction of 17% over 2 years in the group with stenosis greater than 70%. Superior surgical skill is necessary in order to lower the surgical morbidity and mortality rates to a point that the procedure remains beneficial in this cohort.

In order for endarterectomy to be beneficial, there must be a reasonable expectation of survival without other major disability over a 5-year period. Thus subjects with moderately advanced dementia, hepatic failure, or renal failure are generally not considered suitable candidates.

Other considerations help determine which patients carry an increased risk of poor outcome acutely from endarterectomy. As far back as 1975, Sundt and colleagues⁵⁷ recognized that poor or unstable neurologic status, as well as cerebral ischemia within 24 hours of surgery, identified a group at high surgical risk. These authors also related high risk to the following: congestive heart failure, recent cardiac ischemia, marked hypertension, emphysema, age older than 70, and severe obesity. The presence of a contralateral carotid occlusion places subjects at extremely high risk of stroke if left untreated but also carries a high morbidity and mortality risk acutely.⁵⁸

The likelihood of stroke in patients with carotid stenosis rises steadily with increasing severity of stenosis greater than 70%⁵⁶ and then decreases again as the stenosis reaches 94% to 99%. However, surgery remains beneficial in this range.⁵⁹ In addition, hemispheric symptoms predict roughly twice the danger of stroke as do isolated retinal symptoms.⁶⁰ The presence of ulceration in conjunction with stenosis, as detected angiographically, increases the risk of stroke. This effect is most marked when associated with the highest degrees of stenosis and becomes progressively more modest as the degree of stenosis decreases toward 70%.⁶¹

A meta-analysis⁶² has shown that men benefit more from carotid surgery than women. In contrast to Sundt and colleagues⁵⁷ prior findings, there is greater benefit of the procedure in persons older than 75 years. The most important finding to emerge from this report, however, is the dramatic benefit when endarterectomy is performed within 2 weeks of the sentinel event, which diminishes rapidly if surgery is delayed. The previously established surgical practice, to wait for 4 to 6 weeks following stroke or TIA before proceeding with surgery, has become untenable. When severe disability exists, endarterectomy may be reasonably delayed in order to see if sufficient recovery occurs to warrant intervention. However, carotid revascularization, whether by means of endarterectomy or, as discussed later, carotid angioplasty and stenting (CAS), should be undertaken acutely in the absence of major neurologic disability.

Protected CAS has been compared with CEA in a controlled, randomized trial.⁶³ Study participants were 18 years old or older and had either a greater than 50% symptomatic

Box 63.12 High-Risk Criteria for Entry into the SAPHIRE Trial

Clinically significant heart disease: congestive heart failure, abnormal stress test, or need for open heart surgery
Severe pulmonary disease

Contralateral laryngeal nerve palsy
Previous radical neck surgery
Previous radiation therapy to the neck
Carotid restenosis after endarterectomy
Age older than 80 years

SAPHIRE, Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy.

stenosis or a greater than 80% asymptomatic stenosis. They were at high risk, as defined by at least one of the factors listed in Box 63.12.

SAPHIRE (Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy) trial showed a trend favoring CAS for the incidence of death and major ipsilateral stroke, both in the year following intervention. These gains fell short of statistical significance, perhaps because the study was terminated prematurely. The CAS group benefited significantly as far as reduction of hospital length of stay (by 1 day) and reduction in the incidence of laryngeal nerve palsy. Lastly, there was a significant decline in the rate of myocardial infarction (MI) at 1 month following intervention in the CAS group when compared with endarterectomy, caused primarily by a fall in the incidence of non-Q-wave MI. Some of this benefit may reflect the use of clopidogrel in addition to aspirin for 2 to 4 weeks following treatment in the CAS group, whereas the endarterectomy subjects received only aspirin. In summary, the study showed that CAS was not inferior to endarterectomy and perhaps was superior in certain respects. The durability of these results is not known because of limited follow-up. A more important question involves the necessity of intervention. The authors do not systematically distinguish between symptomatic and asymptomatic subjects in their report. Is the benefit of stenting more evident in the symptomatic group? Do the patients with significant systemic illness (cardiac or pulmonary disease) survive long enough to warrant the initial risk of any intervention? There is no control group treated with medical therapy alone for comparison.

In conclusion, SAPHIRE establishes CAS as a practical alternative to endarterectomy in a somewhat heterogeneous high-risk population. It is intuitively attractive because it is less invasive. The clinician must still decide who will benefit from the procedure on an individual basis. CAS will find an important role in the management of subjects with symptomatic carotid stenosis who are awaiting coronary artery bypass surgery. The requisite use of clopidogrel following stenting will mandate a delay of 6 weeks before proceeding with surgery.

Subsequently published studies, SPACE (Stent-Protected Angioplasty versus Carotid Endarterectomy)⁶⁴ and EVA-3S (Endarterectomy Versus Angioplasty in Patients with

Symptomatic Severe Carotid Stenosis),⁶⁵ have been used to cast doubt on the efficacy of CAS in a population of patients with significant symptomatic stenosis, free of such elevated risk. SPACE shows a trend, not reaching statistical significance, toward more stroke and death acutely with CAS than with CEA. Over subsequent 2-year follow-up, the stroke and death risk is the same in either group. However, there appears to be more restenosis in the CAS group, and it is clear that CEA is superior in patients older than 68 years of age. SPACE has flaws. The severity of stenosis was assessed by carotid ultrasound alone, without further validation. Distal protection devices were employed in only a quarter of the CAS patients. Although the authors state that the incidence of periprocedural stroke was not affected by the use of such devices, it is not clear how the decision was taken to use them.

EVA-3S shows that the complication rate of CAS is much higher (9.6%) than the complication rate of CEA (3.6%), without a consequent improvement in natural history over 4-year follow-up. These results may be peculiar to this trial, in which the surgical complication rate was much lower than the CAS complication rate. In this study, CEA seems to be preferable for those older than 70, for men, and for those with stroke either previously or at presentation.

The most recently published trials, CAVATAS (Carotid And Vertebral Artery Transluminal Angioplasty Study)⁶⁶ and CREST (Carotid Revascularization Endarterectomy versus Stenting Trial),⁶⁷ are more definitive. They include both symptomatic and asymptomatic subjects. CAVATAS is an earlier study using a mix of angioplasty and stenting. It shows that endovascular treatment carries a higher risk of small perioperative stroke, although it does protect from cranial nerve injury. Overall, there is no substantive difference between the two treatments. There may be a higher risk of stroke, among both older patients and those patients suffering from cardiac disease, and there may be a higher risk of restenosis with angioplasty. CREST, the largest and most recent trial, reveals an increased risk of stroke acutely with stenting, although endarterectomy acutely is associated with an increased risk of heart attack—this latter risk, however, is not associated with increasing mortality risk. Over 2.5 years of follow-up, there is no significant difference in outcome between the two treatments. Endarterectomy appears to be superior, again, in older patients over 70. Recovery from nonfatal MI is less problematic than recovery from stroke, and the increased stroke risk in the CAS group is early in the patients' course. The results of this study argue against adoption of CAS as an alternative to CEA, particularly as it does not appear to confer a survival benefit, as hoped, to older subjects.

A comment on intracranial angioplasty and stenting is also in order. The realization that warfarin is not superior⁶⁸ to high-dose aspirin for stroke prevention in the setting of symptomatic intracranial arterial stenosis led to the performance of the SAMMPRIS (Stenting and Aggressive Medical Management for Preventing Recurrent Stroke in Intracranial Stenosis) trial.⁶⁹ This was a randomized comparison of intracranial angioplasty and stenting versus intensive medical therapy, including the use of aspirin in conjunction with clopidogrel, for symptomatic intracranial stenosis. The study was stopped prematurely because of a very high risk of periprocedural stroke following intervention, and a very

low risk of stroke in the medically treated group. Consequently, it is difficult to support the routine performance of intracranial angioplasty and stenting on symptomatic vessels, but combined therapy with aspirin and clopidogrel may be considered.

ANTICOAGULATION IN STROKE

Anticoagulants occupy an important but limited place in stroke therapy. The acute use of heparin in unselected stroke patients was studied some years ago but not justified.⁷⁰ More recently, the treatment with warfarin of subjects presenting with symptomatic intracranial stenosis has proved no better than therapy with high-dose (1300 mg daily) aspirin. This use of warfarin produced increased morbidity, in part because of an increased risk of major hemorrhage, primarily gastrointestinal (GI).⁶⁸ When warfarin is given to unselected stroke patients in a population including a slight majority of subjects with lacunar stroke, it confers no advantage relative to aspirin.⁷¹ Warfarin does not reduce the incidence of stroke among subjects with a decreased ejection fraction (<35%) when compared to aspirin.⁷²

Warfarin clearly prevents stroke among subjects suffering from nonrheumatic atrial fibrillation, even if they have never had a stroke or TIA.⁷³ The risk of stroke falls by 64%, a robust and consistent effect that aspirin cannot equal. The CHADS₂⁷⁴ score (Box 63.13) is used commonly to assess the risk of stroke; the higher the score, the higher the risk. Individuals younger than 65 years of age with atrial fibrillation who have no significant vascular risk factors are at low risk and do not need anticoagulation. Such individuals are rare in clinical practice. The risk of systemic hemorrhage and of ICH with warfarin use in this setting is low. A combination of clopidogrel and low-dose aspirin⁷⁵ is inferior to warfarin in stroke prevention among patients with atrial fibrillation. The bleeding risk is actually lower with warfarin than with the antiplatelet combination. However, combination therapy with aspirin and clopidogrel is superior to aspirin alone among patients thought unsuitable for anticoagulant use,⁷⁶ although the combination does raise the risk of major hemorrhage somewhat.

Individuals with atrial fibrillation who sustain a minor stroke or TIA have a high stroke risk (12% per year), which

Box 63.13 Components of the CHADS₂ Score

Congestive heart failure	1 point
Hypertension (consistently >140/90 mm Hg or on therapy)	1 point
Age older than 75 years	1 point
Diabetes mellitus	1 point
Prior stroke or TIA	2 points

CHADS₂, Congestive heart failure, Hypertension, Age >75, Diabetes mellitus, and prior Stroke or transient ischemic attack; TIA, transient ischemic attack.

falls to 4% per year upon treatment with warfarin. A 2.8% yearly risk of all bleeding complications with warfarin exists, as opposed to 0.7% with placebo. Aspirin is nearly as safe as placebo, but it reduces the stroke risk only modestly.⁷⁷ It remains uncertain when in the course of stroke to initiate anticoagulant therapy. A randomized trial⁷⁸ has compared a form of low-molecular-weight heparin (dalteparin) to 160 mg of aspirin in patients with stroke and atrial fibrillation. Treatment began within 30 hours of stroke onset, and the risk of recurrent stroke at 14 days was determined. This proved to be 8%. Dalteparin was equivalent to aspirin. This study was not powered to demonstrate a more modest beneficial effect of dalteparin, which may or may not be present. Nevertheless, this study urges caution on those who would treat completed stroke acutely with anticoagulants. The exclusion criteria for the study serve as a guideline as to when not to treat with anticoagulants. Patients with severe strokes and those with marked elevation of blood pressure were not entered. Acute anticoagulation in the face of stroke should be withheld if there is a sizable infarct as measured by the NIHSS (perhaps a score of ≥ 12) or on CT ($> \frac{1}{3}$ of MCA territory), which could progress to herniation and death as a result of hemorrhage into the infarct bed. The 185/110 mm Hg cutoff measurement used in the NINDS tPA trial may give some idea of the range of hypertension that would cause one to withhold acute treatment with anticoagulants.

In contrast, one should move quickly to anticoagulation following a TIA occurring in conjunction with atrial fibrillation or any other recognized indication for anticoagulation. Minor strokes that begin with potentially devastating deficits but go on to resolve substantially should receive anticoagulation if its use is indicated. These recommendations seem appropriate in view of the high risk of stroke recurrence in atrial fibrillation, as cited previously.⁷⁷

Other indications for anticoagulation appear in **Box 63.14**. Some, such as the presence of rheumatic heart disease with atrial fibrillation, prosthetic heart valve, or deep venous thrombosis (DVT), are long established. Anticoagulation carries more urgency when a DVT coexists with a communication across the atrial septum, such as patent foramen ovale (PFO), because there is risk of both recurrent stroke and pulmonary embolism.

The utility of warfarin is limited by the need for regular blood work, and by difficulty in regulating its dosage. Factor II and factor Xa inhibitors have recently been studied for stroke prevention in the setting of atrial fibrillation. Dabigatran (Pradaxa) and rivaroxaban (Xarelto) are marketed in

the United States. Another, apixaban, reduces the risk of stroke⁷⁹—when compared to aspirin—in patients deemed unsuitable for warfarin use, without an increase in major or intracranial hemorrhage. When compared directly to warfarin, apixaban reduces the risk not only of stroke but also of both intracranial hemorrhage and of serious hemorrhage.⁸⁰ Rivaroxaban⁸¹ appears equivalent to warfarin in stroke prevention, and it is less likely to produce intracranial hemorrhage but carries a higher risk of major GI hemorrhage. Dabigatran, at the dosage of 150 mg daily,⁸² is associated with a smaller stroke risk and, like rivaroxaban, a lesser risk of intracranial hemorrhage but a higher risk of major GI hemorrhage, when compared to warfarin.

The main concern with these agents is the lack of means to reverse their effect in the setting of hemorrhage. One patient taking dabigatran has died⁸³ from relatively minor head trauma leading to progressive intracranial hemorrhage. It may be possible to reverse the effects of rivaroxaban, but not dabigatran, through the use of prothrombin complex concentrate,⁸⁴ although dabigatran may be cleared through dialysis.⁸⁵ Fortunately, these agents have short half-lives and are cleared rapidly.⁸⁶ Nevertheless, care is enjoined in their use, both in the setting of renal insufficiency, and in conjunction with aspirin.⁸⁷ Hemorrhage in patients using factor II and factor Xa antagonists will remain troublesome until means to reverse the anticoagulation produced by these agents are developed, together with the capability to monitor the process in real time. For now, fear of this complication will limit the use of these agents.

Venous sinus thrombosis is an uncommon condition that manifests with headache and papilledema, as well as focal symptoms, and often leads to ICH.⁸⁸ Diagnosis is by magnetic resonance venography.⁸⁹ Treatment is with heparin acutely, even in the presence of ICH.⁹⁰ More recent reports have established the safety of low-molecular-weight heparin followed by 3 months of warfarin therapy for this condition, although only a trend toward favorable outcome emerged.⁹¹ Retrograde thrombolysis through the venous system with tPA in conjunction with IV heparin is effective in more serious cases.⁹²

Spontaneous dissection of the carotid and vertebral arteries is the subject of a review by Schievink.⁹³ This is a significant cause of stroke in younger individuals. Carotid dissection often presents with neck pain, radiating to the head, and with components of Horner's syndrome (ptosis, miosis, and anhidrosis). Vertebral dissection presents with pain in the neck or back of the head initially. Either may proceed to cerebral infarction or to retinal infarction in the case of carotid dissection. MRA diagnoses carotid dissection quite accurately, and vertebral dissection less so.⁹⁴ Anticoagulation is commonly employed but has not been subjected to a rigorous trial. The presence of dissection does not appear to contraindicate the performance of thrombolysis by whatever route.⁹⁵

Box 63.15 lists the hypercoagulable states.⁹⁶ Most of these lead mainly to the development of venous thrombosis, although antiphospholipid antibodies and the lupus anticoagulant may produce both venous and arterial thrombosis. The duration of anticoagulation rests on the judgment of the treating physician. Three to 6 months of therapy is commonly undertaken if the episode of thrombosis is isolated.

Box 63.14 Indications for Anticoagulation in Stroke

- Atrial fibrillation, with or without rheumatic heart disease
- Prosthetic heart valve
- Deep venous thrombosis, with or without the potential for paradoxical embolus
- Hypercoagulable state
- Venous sinus thrombosis
- Arterial dissection

Box 63.15 Causes of Hypercoagulable States

Protein C deficiency
 Protein S deficiency
 Antithrombin III deficiency
 Factor V Leiden
 Prothrombin gene mutation
 Antiphospholipid antibodies
 Lupus anticoagulant

ANTIPLATELET AGENTS IN STROKE

Secondary stroke prevention continues to depend on aspirin, as it has for many years. A meta-analysis carried out in 1994⁹⁷ showed that antiplatelet therapy, primarily with aspirin, reduces the risk of stroke, MI, and vascular death in aggregate by 25%. This analysis did not discriminate among those subjects treated primarily for heart disease and those treated for cerebral ischemia. A similar analysis⁹⁸ focusing only on the latter found a lesser benefit of aspirin, on the order of 13%. The optimal dosage of aspirin remains unknown. One study⁹⁹ failed to show a difference in outcome when comparing dosages of 30 mg and 283 mg. Another¹⁰⁰ revealed no difference in efficacy between 300 mg and 1200 mg of aspirin a day. In both reports, the lesser dosage led to fewer significant bleeding episodes.

The limited effect of aspirin on stroke recurrence, coupled with the seeming failure of increases in dosage to further reduce stroke risk, led to a search for other antiplatelet agents. Ticlopidine enjoyed brief popularity but was found to produce agranulocytosis (<1500 neutrophils/ μL) in 2.4% of subjects, which was severe ($<450/\mu\text{L}$) in 0.8%.¹⁰¹ Thrombotic thrombocytopenic purpura, fatal in 4 of 13 cases, also occurred.¹⁰² Both the need for regular blood monitoring and the risk of a severe and potentially fatal complication led to the virtual abandonment of this agent.

Another thienopyridine, clopidogrel, was studied in the CAPRIE (Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events) trial.¹⁰³ It exhibited minimal benefit compared with aspirin in preventing vascular events both in patients presenting with stroke and in those manifesting with MI. Nevertheless, it was approved for use primarily on the strength of its ability to reduce the development of vascular events in subjects presenting with peripheral arterial disease. It has won wide support and has subsequently proved quite useful, administered together with aspirin, in the treatment of unstable angina¹⁰⁴ and acute MI^{105,106} and following stent placement in the coronary vessels.¹⁰⁷

Physicians have used clopidogrel in conjunction with aspirin for stroke prevention in the expectation that the combination would prove superior to clopidogrel in isolation. However, a comparison between the use of 75 mg of aspirin together with 75 mg of clopidogrel and the use of clopidogrel alone revealed no benefit of combination therapy, just a heightened risk of GI hemorrhage.¹⁰⁸ Another study¹⁰⁹ failed to show a benefit of combination therapy when compared with the use of aspirin alone in preventing stroke, MI, or vascular death. In addition, the risk of “moderate” hemorrhage was increased in the group receiving

combination therapy. Patients, in order to enter this study, had to have either established vascular disease or, in a minority, multiple vascular risk factors. The study as published does not assess the risks or benefits of combination therapy relative to aspirin in subjects randomized for stroke alone. Nevertheless, the results do not support the chronic use of combination therapy in the prevention of acute vascular syndromes and death of vascular origin. Perhaps combination therapy may be useful in the setting of acute cerebral ischemia, as it is for acute coronary syndromes with ST-segment elevation.^{105,106} Certainly the use of aspirin is recognized as beneficial in acute stroke when instituted within 48 hours,¹¹⁰ and one may imagine, on the basis of the cardiac data, that clopidogrel may also benefit stroke acutely. A study is ongoing¹¹¹ to address this possibility, but results will not be available soon.

An alternative to the use of aspirin or clopidogrel is the combination of low-dose aspirin in conjunction with extended-release dipyridamole (ASA + ER/DP). The initial aspirin and dipyridamole study, ESPS (European Stroke Prevention Study),¹¹² showed a striking benefit of the combination of 990 mg of aspirin and 75 mg of dipyridamole daily in reducing stroke by 38%. This result raised the question of whether the high aspirin dosage or the addition of dipyridamole was responsible for the dramatic improvement in outcome. A second trial, ESPS-2,¹¹³ revealed a similar benefit using a regimen of 50 mg of aspirin and 400 mg of ER/DP per day. The effect of the two agents was additive. However, there was no improvement in mortality rate or in the rate of MI in any of the treatment groups (ASA, ER/DP, or ASA + ER/DP) when compared with placebo in ESPS-2. This contrasts with the results of ESPS, in which combination therapy did reduce both the rate of vascular death and, in the intention-to-treat analysis, that of MI. Thus both the active regimen used in ESPS and the combination therapy used in ESPS-2 significantly reduced the rate of recurrent stroke. However, only in ESPS, which used a much higher aspirin dosage, was there a reduction in the rate of MI and vascular death.

As already noted, previous studies^{99,100} have not revealed significant differences in outcome on the basis of the aspirin dosage used but the numbers enrolled in these trials are relatively modest and differences cannot be definitively excluded.

A recent large randomized trial with roughly 20,000 patients (PROFESS [Prevention Regimen for Effectively avoiding Second Strokes]) compared ASA + ER/DP to clopidogrel in the prevention of stroke, MI, and death among patients presenting with stroke.¹¹⁴ The two treatments proved equivalent overall, but the rate of ICH was increased in the ASA + ER/DP group. Because ASA + ER/DP needs to be taken twice daily, has more side effects (headache, primarily), and has no cost advantage, the study has not led to its widespread use.

In conclusion, the area of antiplatelet therapy for stroke has evolved. Clopidogrel remains the drug of choice under certain restricted circumstances (Box 63.16). Clinicians often change therapy from one antiplatelet agent to another following the development of a cerebral ischemic event, but one must expect a significant failure rate with any of these agents. Whether such a strategy is beneficial is unclear. Aspirin will remain the agent of choice for most patients,

Box 63.16 Indications for the Use of Clopidogrel after Cerebral Ischemia

Recent acute coronary syndromes
Recent stent placement
Absolute aspirin intolerance including aspirin allergy
Coexistent symptomatic peripheral arterial disease

particularly when one considers the cost of the alternatives. Combination therapy with aspirin and dipyridamole may find a niche in individuals with cerebrovascular disease who are at risk for the development of GI hemorrhage.

PATENT FORAMEN OVALE

PFO is a recently recognized cause of cardiac embolization to the brain. PFO is detected by two-dimensional echocardiography with injection of agitated saline or by transesophageal study. In one report it appeared in 18% of young control subjects and in 40% of subjects with cryptogenic stroke. PFO was more common as well in younger as opposed to older patients with cryptogenic stroke (stroke of unknown origin following standard evaluation).¹¹⁵ The combination of PFO with atrial septal aneurysm in stroke patients younger than the age of 55 is associated with a high (15.2% over 4 years) risk of recurrent stroke.¹¹⁶ Others¹¹⁷ have found a large diameter (>4 mm) of the PFO to predict increased risk of stroke recurrence. PFO can be treated with warfarin, aspirin, surgical closure, and now endovascular closure. No data suggest conclusively that one treatment surpasses the others,¹¹⁸ as confirmed by the recently published CLOSURE I trial.¹¹⁹ In this study, PFO closure did not lead to fewer strokes than did medical therapy. Neither the size of the interatrial shunt nor the presence of an associated atrial septal aneurysm influenced the results. Moreover, PFO closure, aside from procedural complications, was related to a significantly increased risk of atrial fibrillation. At this time, closure of a PFO may be indicated in the absence of another explanation for multifocal infarction.

MASSIVE HEMISPHERIC CEREBRAL INFARCT

Infarction of the entire MCA territory leads to the development of the “malignant MCA” syndrome.¹²⁰ This major injury leads to death in 78% of cases in the first week after the ictus, as the result of cerebral edema leading to transtentorial herniation, and the survivors are quite disabled. Brain swelling peaks at 3 to 5 days following stroke onset.

The presence of early CT changes, namely, hypodensity of more than 50% of the MCA territory, indicates a poor prognosis.¹²¹ In the absence of appropriate intervention, midline displacement of the pineal gland greater than 4 mm predicts death reliably. Large volume of infarction (Fig. 63.5) and displacement of the septum pellucidum also indicate a poor outcome.¹²² At initial presentation, aphasia

Figure 63.5 Massive middle cerebral artery (MCA) infarct. Hypodensity of the entire right MCA territory (*open arrows*) and compression of the right lateral ventricle (*white arrows*) are demonstrated.

or neglect may be present, depending on the hemisphere affected. Characteristically, the patients display hemiplegia and a dense hemisensory loss, although the leg may be relatively spared. Quite often, there is a forced eye deviation and hemianopia may coexist. Mortality rate is higher in older individuals with this syndrome,¹²³ but transtentorial herniation is a more significant cause of death among younger subjects with ischemic stroke.¹²⁴ Presumably younger individuals have less cerebral atrophy and less room within the cranial vault to accommodate brain swelling.

Treatment of this syndrome has so far proved disappointing, as reviewed by different authors.¹²⁵⁻¹²⁷ The review by Wijdicks¹²⁷ is particularly comprehensive. Standard therapies include hyperventilation and the administration of IV mannitol. Mannitol is a dehydrating agent, an osmotic diuretic, which aims at reducing cerebral volume and thus ICP. It is given initially at a dosage of 1 g/kg, followed by recurrent dosing four times daily with 0.25 to 0.5 g/kg. The goal of therapy is a serum osmolality of 315 to 320 mOsm/L. Mechanical ventilation with hyperventilation produces hypocarbia, which leads to cerebral vasoconstriction, reduced cerebral blood volume, and decreased ICP. The target range for P_{aCO_2} is not well defined. Steiner and colleagues¹²⁶ state that lowering P_{aCO_2} from “35 to 29 mm Hg lowers ICP by 25% to 30% in most subjects.” The benefit of these interventions in clinical practice appears to be short-lived. Because hyperventilation is associated with decreased blood flow, it should be viewed as a temporizing measure only.

More promising therapies include hypothermia and decompressive hemicraniectomy. Hypothermia in one pilot trial¹²⁸ lowered ICP temporarily when instituted within 14 hours of onset of major MCA stroke. Hypothermia has also been employed¹²⁹ shortly after thrombolysis. The use of a device placed in the inferior vena cava lowers body temperature much more quickly than surface cooling,¹³⁰ although there is a concern regarding the development of DVT. Hypothermia to 33° C for 24 hours, following tPA administration within 6 hours of stroke onset, is safe, apart from an increased risk of pneumonia.¹³¹ A larger randomized trial of hypothermia following thrombolysis, ICTuS2/3 (Intravascular Cooling in the Treatment of Stroke 2/3 Trial),¹³² is under way.

Decompressive hemicraniectomy with durotomy in early studies appeared beneficial when compared with medical treatment,¹³³ particularly when intervention occurred before the appearance of signs of incipient herniation.¹³⁴ However, the surgically treated patients in these two reports differed significantly from the control patients. The surgical patients were younger, and subjects with large left hemispheric infarcts producing global aphasia were not considered for surgery. Some, if not all, of the benefit in the surgically treated group may be explained by this imbalance between the control and treated groups. More recently, three randomized trials have been carried out,¹³⁵⁻¹³⁷ and a preplanned pooled analysis¹³⁸ of their results published. Two of these studies were terminated prematurely,^{135,136} all the studies revealed reductions in mortality rate, but benefits in functional outcome were lesser and not consistently significant. The pooled analysis, looking at the benefit of hemicraniectomy in patients younger than 60 years of age treated within 48 hours, showed significant benefits both in mortality rate and in functional outcome, such that hemicraniectomy has been adopted into general practice. A further study, DESTINY II,¹³⁹ will examine the efficacy of this intervention among subjects older than 60.

Surgical intervention also exists for cerebellar infarction, which, when large, may expand and place pressure on the brainstem.¹⁴⁰ Both ventriculostomy to relieve hydrocephalus acutely and decompressive craniotomy are employed. The main determinant of survival and recovery is the absence of coma on presentation. Surgery is the accepted treatment, but the exact timing of intervention remains uncertain.¹⁴¹

CRITICAL CARE CONSULTATION

Critical care consultation for stroke patients is indicated for a number of reasons (Box 63.17).

SUMMARY

In conclusion, stroke therapy is advancing significantly. Thrombolysis and endovascular therapy have developed over the past 20 years. Advances in radiology have improved imaging of strokes and of blood vessels and may come to play a role in patient selection for acute intervention. Endarterectomy has become established in the treatment of carotid disease and angioplasty and stenting for the treatment of high-risk cases. New anticoagulants have appeared,

Box 63.17 Indications for Critical Care Consultation

Intubation and mechanical ventilation
Administration of continuous infusions of antihypertensive agents
Administration of pressor agents
Monitoring not feasible in other settings
Intraventricular drainage
Induction and maintenance of hypothermia

although they are not free of risk. No longer is aspirin the only antiplatelet agent available. Decompressive surgery can save lives that would otherwise be lost. Hypothermia may soon join these other therapies in the physician's armamentarium. Much of this activity has taken place in the critical care unit. One may hope that the next 20 years will bring further revelations. As our means for intervention increase, so will the role of critical care in reducing death and disability from stroke.

KEY POINTS

- Determine time of onset of all new strokes.
- Consider IV thrombolysis with tPA if within 3 hours of onset.
- Consider IA thrombolysis for basilar thrombosis or if within 6 hours of stroke onset.
- Consider rescue therapy with mechanical clot extraction or IA thrombolysis.
- Observe published guidelines for blood pressure control.
- Use MRI and MRA or CT and CTA to visualize the brain and its vasculature.
- Proceed promptly to carotid endarterectomy or carotid angioplasty and stenting.
- Apply anticoagulants when indicated.
- Use antiplatelet agents according to specific indications.
- Treat malignant MCA infarction with craniectomy.
- Consider surgical intervention for large cerebellar infarcts.

MANAGEMENT

Myasthenia Gravis

Guillain-Barré Syndrome

Acute neuromuscular disorders may be suspected in patients with acute hypercapnic respiratory failure. They usually present with acute, subacute, or chronic dyspnea, tachypnea, and tachycardia. They may also have associated oropharyngeal weakness manifested by nasal voice, poor cough, and problems in handling secretions. Neuromuscular respiratory failure is associated with the use of accessory muscles of respiration and paradoxical breathing. Neuromuscular weakness-induced acute respiratory failure seen in the intensive care unit (ICU) involves patients with Guillain-Barré syndrome (GBS) or an exacerbation of previously diagnosed myasthenia gravis (MG). The management of patients with these disorders is different from that of patients with primary or secondary pulmonary disease and requires challenging decisions on all aspects of care.

This chapter provides a concise overview of pathophysiology, diagnosis, and optimal management of acute neuromuscular respiratory failure as a result of GBS and MG.

CLINICAL PRESENTATION

MYASTHENIA GRAVIS

MG is an autoimmune disease of defective neurotransmission leading to fatigable muscle weakness. The incidence is 0.5 to 5 cases per 100,000. Its pathogenesis can be summarized briefly as an antibody reaction at the antigen epitopes of the acetylcholine receptor (AChR), eventually leading to destruction and simplification of the junctional fold and widening synaptic cleft.¹ Onset may be at any age but tends

to be earlier in women (mean age 28 years) than in men (mean age 42 years). MG results in either transient or persistent focal or generalized fatigability or weakness. In more than half of the cases, the initial symptoms involve the eyes, presenting as ptosis, diplopia, or ophthalmoparesis.

Myasthenic crisis is arbitrarily defined as MG complicated by respiratory failure requiring mechanical ventilation or delayed extubation for more than 24 hours in an already intubated myasthenic patient. It is seen in 10% to 60% of MG patients typically within the first 12 months of disease onset.^{2,3} The need for ventilatory assistance usually follows onset of weakness of diaphragmatic or accessory respiratory muscles, but mechanical ventilation also may become necessary because of airway collapse from oropharyngeal muscle weakness, stridor from vocal cord weakness, or the inability to clear secretions.⁴ One third of the patients may have recurrent myasthenic crises.⁵

Common precipitating causes include viral or bacterial infection in 48% (pneumonia, respiratory infection, or sepsis), aspiration in 10%, reduction of pyridostigmine in 19%, and initiation of steroids in 7% patients.^{6,7} Changes in medication may relate to the recent addition of corticosteroid, dose reduction, or high-dose acetylcholinesterase inhibitors. Other precipitating factors may be physical trauma, surgical procedures (particularly thyroidectomy), pregnancy, emotional stress, or exposure to drugs with neuromuscular blocking action such as aminoglycosides. No precipitating factor can be identified for myasthenic crisis in 30% patients.^{6,7}

Myasthenic crisis requires urgent evaluation and treatment. The mortality rate for myasthenic crisis has declined

from a nearly always fatal outcome in the 1920s to 4.5% in the new millennium with the discovery and application of acetylcholinesterase compounds, mechanical ventilation, immunosuppressive agents, and more recently, plasma exchange and intravenous immunoglobulin (IVIG).⁸ Timely diagnosis and appropriate treatment with IVIG or plasma exchange for patients with bulbar and respiratory muscle weakness have helped to reduce the mortality rate and total hospital stay from myasthenic crisis, but care of a patient with MG may be prolonged and complicated. Median hospital stay after a myasthenic crisis is 4 to 6 weeks.

GUILLAIN-BARRÉ SYNDROME

GBS is an acute, monophasic, inflammatory, demyelinating polyneuropathy, also known as acute inflammatory demyelinating polyneuropathy (AIDP). Its incidence is 1 to 2 cases per 100,000 people and remains fairly constant across the continents. GBS commonly is precipitated by an infection, but the immunopathogenesis has remained elusive since its original description in 1916. *Campylobacter jejuni*, cytomegalovirus, and Epstein-Barr virus predominate as preceding infection pathogens.⁹ Symptoms and signs usually progress within 1 to 2 weeks.

The diagnosis of GBS often is straightforward. Severe back pain and limb paresthesias, starting in the ankles and wrists with a “tight band” feeling, are typical presenting signs. The paresthesias gradually scatter over the limbs and move proximally. Although paresthesias are often the presenting symptoms, sensory modalities remain normal to mildly impaired. Weakness begins in the more proximal muscles, causing difficulty with climbing stairs and getting out of a chair, and is notable 1 or 2 days after the onset of paresthesias. Symmetrical weak muscles are accompanied by depressed or absent deep tendon reflexes. Mostly legs are more involved than arms, creating the impression of an ascending paralysis. Facial and oropharyngeal muscles are affected in 50% of the cases, and weakness of these muscle groups may be the initial manifestation. Patients may also have staccato speech (ability to speak only short sentences) and small tidal volume with increased respiratory rate. Respiratory failure, if it occurs, commonly appears within

1 week after the onset of paresthesias.¹⁰ Dysautonomia occurs in up to 70% of the cases, manifesting as arrhythmias, tachycardia, diaphoresis, labile blood pressures, urinary retention, or ileus.

Cerebrospinal fluid (CSF) analysis typically shows high protein content with a normal white blood cell count (the classic albuminocytologic dissociation). More than 10 white blood cells may be seen although this number is unusual but is more common in associated disorders such as Lyme disease, sarcoidosis, and AIDS.¹¹ Electrophysiologic studies are more useful for diagnosis and less useful for prognostication. The typical finding involves demyelination seen as conduction block or increased conduction velocities. Specific tests for proximal nerve involvement seen early in the disease course include recording of F waves and nerve signal abnormalities like dispersion or dropout in signal. Prolonged F wave may be the only finding early on. Needle electromyography may be normal in the first 2 weeks. Recovery often starts after the second week. Progression over 8 weeks more likely suggests the diagnosis to chronic inflammatory demyelinating polyneuropathy (CIDP).

ACUTE NEUROMUSCULAR RESPIRATORY FAILURE

PATHOPHYSIOLOGY

During respiration, lungs can expand and recoil in two ways: by downward and upward movement of the diaphragm to lengthen and shorten the chest cavity, and by elevation and depression of the ribs to increase and decrease the anteroposterior diameter of the chest (Fig. 64.1). Normal quiet breathing is largely accomplished by contraction of the diaphragm.

In neuromuscular respiratory failure, ventilatory function is compromised through two mechanisms: (1) respiratory muscle weakness or fatigue (involving the diaphragm and the intercostal muscles), and (2) oropharyngeal weakness, which leads to obstruction of the upper airway and inability to clear secretions. The neuromuscular respiratory failure follows the following pattern: failure of diaphragm and

Figure 64.1 Normal mechanism of breathing and paradoxical breathing in neuromuscular respiratory failure. Normal position of diaphragm (A). Normal mechanism: during inspiration, a downward movement of the diaphragm pushes the abdominal contents down and out as the rib margins are lifted and moved out, causing both the chest and abdomen to rise (B). Paradoxical breathing: with diaphragmatic weakness or paralysis, the diaphragm moves up rather than down during inspiration, and the abdomen moves in, contracting during chest rise (C).

intercostal muscles followed by use of accessory muscles resulting in hypoventilation and atelectasis, further leading to shunting and hypoxia. Respiratory muscle weakness leads to shallow low tidal volume breathing and poor gas exchange leading to tachypnea and later hypercapnia. Oropharyngeal muscle weakness leads to aspiration pneumonitis and could further worsen the hypoxia. Clinically, the patient will pause frequently during speech and breathlessness improves in an upright position (Fig. 64.2).

Pulmonary studies typically reveal a pure ventilatory defect with otherwise normal pulmonary parenchyma. The ventilatory defect may worsen with the development of atelectasis. Neuromuscular weakness of the respiratory muscles is characterized by the inability to generate or maintain normal respiratory pressures. The degree of involvement of the inspiratory and the expiratory muscles is variable, and the clinical manifestations reflect the compromise of both muscle groups. Ventilation remains intact until diaphragm involvement becomes significant.

The first indication of diaphragmatic weakness is alveolar hypoventilation and impaired CO₂ exchange. These changes are followed by an increase in respiratory rate as a compensatory mechanism to attempt to maintain minute ventilation. Later, accessory muscles of ventilation are recruited in response to increased ventilatory demand. Paradoxical breathing, also known as thoracoabdominal asynchrony, occurs with severe respiratory weakness. Normally, the abdomen and chest expand and contract in a synchronized fashion. During inspiration, a downward movement of the diaphragm pushes the abdominal contents down and out as the rib margins are lifted and moved out, causing both chest

and abdomen to rise. With diaphragmatic weakness or paralysis, the diaphragm moves up rather than down during inspiration, and the abdomen moves in, contracting during chest rise. This is known as “paradoxical breathing” and can be visualized with fluoroscopy (see Fig. 64.1). The ventilatory drive response to an increase in CO₂ in patients with GBS and MG has been studied and was found to be unlikely to contribute to hypoventilation during ventilatory failure.¹² Ventilatory drive increases during acute hypoventilation, and the ventilatory drive response to CO₂ remains intact, even when the minute ventilation response to CO₂ is poor.

Although the upper airway muscles do not contribute directly to chest expansion or collapse, they are essential for keeping the airways open during respiration. They play an important role in preventing collapse of the pharynx during inspiration and preventing aspiration during swallowing. With the exception of laryngeal muscles, oropharyngeal muscles have a higher proportion of fast fibers. Their weakness can be seen early on in MG and later in GBS (Fig. 64.3). Slow fibers have a higher fatigue resistance than fast fibers due to their highly oxidative metabolism. The diaphragm has an equal proportion of slow and fast muscle fibers, which in association with small fiber size, high aerobic oxidative enzyme activity, and large number of capillaries make it resistant to fatigue.¹³

CLINICAL EVALUATION

The first step in evaluation of neuromuscular respiratory failure is assessment of clinical features along with bedside pulmonary function tests.

Clinical predictors of worsening neuromuscular respiratory failure in both GBS and MG patients include difficulty handling secretions, restlessness, use of accessory muscles of respiration, rapidly progressing neuromuscular failure, and increasing oxygen requirements. Aspiration or major atelectasis on chest radiograph, evidence of respiratory infection, and failure to improve on bilevel positive airway pressure (BiPAP) are other indicators for worsening neuromuscular respiratory failure.

Frequent (at least four times daily) assessment of pulmonary function should be instituted using bedside spirometry. Although bedside spirometry is often done for respiratory evaluation in both MG and GBS, it is less reliable for MG as patients' results often vary depending on their activity level prior to the testing. Patients should be coached for spirometry as they may have difficulty making an adequate seal around the mouthpiece of the spirometer. Poor effort and leak around the mouthpiece may lead to lower vital capacity (VC), maximal inspiratory pressure (P_{imax}), and maximal expiratory pressure (P_{emax}) than expected based on arterial blood gas (ABG) and chest x-ray studies. VC, the volume of exhaled air after maximal inspiration, is 60 to 70 mL/kg in normal persons, and is determined primarily by the size of the thorax and lungs. In neuromuscular respiratory failure, reduction of VC to 30 mL/kg is associated with weak cough, accumulation of oropharyngeal secretions, atelectasis, and hypoxemia. Another measure of respiratory muscle strength is the ability to generate negative pressure with inspiratory effort. In normal persons, respiratory muscles cause pleural and alveolar pressures to change by approximately 3 cm H₂O during the breathing cycle. Maximal

Figure 64.2 Clinical features of imminent respiratory failure.

Figure 64.3 Clinical examination of pertinent features in myasthenia gravis. **A**, Biting on tongue depressor to assess masseter weakness. **B**, Puffing out cheeks and resisting pressure from examiner's fingers. **C**, Ptosis and typical snarl of bifacial weakness. **D**, Pushing away tongue depressor with tongue.

Box 64.1 Pathophysiologic Changes with Neuromuscular Failure

- Normal respiratory function is present with VC of 65 mL/kg.
- Poor cough is evident with accumulation of secretions and with VC of 30 mL/kg.
- With VC of 20 mL/kg, the sigh mechanism is impaired, and atelectasis and hypoxia develop.
- Sigh is lost with VC of 15 mL/kg, and atelectasis and shunting appear.
- Hypoventilation starts with VC of 10 mL/kg.
- Hypercapnia develops with VC between 5 and 10 mL/kg.

VC, vital capacity.

pressure generation can be determined by blocking the upper airway and recording mouth pressure changes during inspiratory effort. P_{imax} measures the strength of the diaphragm and other muscles of inspiration and reflects the ability to maintain normal lung expansion and avoid atelectasis. A maximal P_{imax} is −114 cm H₂O in young men and −67 cm H₂O in young women (normal, exceeding −70 cm H₂O). P_{emax} measures strength of the muscles of expiration and correlates with strength of cough and ability to clear secretions from the airway¹² (Box 64.1). P_{emax} averages 160 cm H₂O in young men and 95 cm H₂O in young women (normal, greater than 100 cm H₂O). This means that the respiratory muscles are capable of generating more than 30 times the amount of force necessary for tidal breathing.¹⁴ Worsening bedside spirometry can identify MG and GBS patients requiring invasive or noninvasive mechanical ventilation (NMV). An easy way to remember bedside pulmonary indicators of respiratory failure in GBS is the so-called 20/30/40 rule, with VC less than 20 mL/kg, a P_{imax} less negative than −30 cm H₂O, and a P_{emax} less than 40 cm H₂O.

A simple bedside test, asking patients to count to 20 without the need of an additional respiration, may identify early neuromuscular respiratory weakness.

Bedside ABG may be helpful for to look for hypercapnia and hypoxia. It is important to recognize that in patients with neuromuscular respiratory failure and imminent respiratory arrest, ABG analysis results often remain relatively normal until severe respiratory muscle weakness or total failure develops. ABG analysis performed early after development of a rapid, shallow breathing pattern may show a decreased arterial partial pressure of carbon dioxide (P_{aCO₂}). This change is followed by progressive inspiratory muscle weakness, leading to hypoventilation and hypercapnia. The P_{CO₂} in alveolar gas or arterial blood is inversely related to the alveolar ventilation. If the alveolar ventilation is halved, the P_{CO₂} doubles while the CO₂ production rate remains constant. Microatelectasis and alveolar collapse also can develop in patients unable to take deep breaths, leading to ventilation-perfusion mismatch and decreased arterial partial pressure of oxygen (P_{aO₂}). Portable chest radiograph may show poor lung expansion, aspiration, and atelectasis.

Because in myasthenic crisis most of the identified causes are related to infection or medication changes, medication reconciliation, physical examination, chest radiograph, complete blood count, and cultures (blood, sputum, and other cultures depending on the clinical presentation) should be part of the initial workup. Respiratory failure in GBS patients is part of disease progression and may or may not have a precipitating cause. Other causes of respiratory dysfunction in bedridden ICU patients, such as pulmonary embolism, pneumonia, fluid overload, and cardiac failure, should be considered in the appropriate setting.

NONINVASIVE VENTILATION: BILEVEL POSITIVE AIRWAY PRESSURE

Traditionally, patients with acute neuromuscular respiratory failure are ventilated by invasive mechanical ventilation. Prolonged endotracheal intubation, however, is associated

with discomfort and ventilator-associated complications.⁷ In both MG and GBS, mortality and morbidity rates are strongly tied to the duration of invasive mechanical ventilation. NMV is being used increasingly to manage acute deterioration in patients with neuromuscular failure.¹⁵ Downsides of NMV are, in patients with associated bulbar weakness, upper airway collapse with increased airway resistance, and lack of airway protection from secretions.

Noninvasive mechanical ventilation using BiPAP ventilation (inspiration and expiration pressure application) in acute respiratory failure caused by MG was shown to be effective in a group of patients with MG from the Mayo Clinic.¹⁵ The mean duration of BiPAP was 4.3 days. NMV averted endotracheal intubation in 14 cases of severe MG exacerbation, even in the presence of bulbar weakness. In this study, the presence of hypercapnia (PaCO_2 greater than 45 mm Hg) at onset predicted NMV failure and subsequent intubation. Lower P_{Emax} on arrival was associated with longer ventilator duration.¹⁵ In contrast with the findings with MG, data on use of NMV in GBS is scarce. One study warned against its use because improvement following initiation of NMV did not prevent emergency intubation in patients with GBS.¹⁶

MECHANICAL VENTILATION: ENDOTRACHEAL INTUBATION

MYASTHENIA GRAVIS

Although several parameters traditionally have been suggested for intubation in MG patients (VC less than 15 mL/kg, P_{imax} less than -30), the fluctuating nature of the disease and frequently associated facial muscle weakness give these parameters limited positive predictive power.^{17,18} P_{imax} worsening of 30% or more may predict patients at higher risk of requiring mechanical or noninvasive ventilation.¹⁸ Ventilatory support is unlikely to be needed when VC is more than 20 mL/kg.

Assessment of respiratory function in MG patients should use a range of criteria including symptoms of breathlessness, paradoxical abdominal wall motion, bulbar nerve palsy, and ABG analysis to look for the presence of hypercapnia or hypoxia. As discussed earlier, patients with PaCO_2 greater than 45 mm Hg usually are unresponsive to noninvasive ventilation and should be managed with endotracheal intubation. However, hypercapnia alone is not always a mandatory indication for mechanical ventilation, and this decision should take into consideration the patient's ease of respiration, level of consciousness, and stability of PaCO_2 .¹⁸ MG patients who are positive for anti-MuSK (muscle-specific kinase) antibodies are at a greater risk for the development of respiratory compromise and bulbar symptoms and should be watched more closely.¹⁹⁻²¹

Invasive mechanical ventilation in patients with MG can be avoided in a majority of cases with early implementation of rapid immunomodulatory treatments and noninvasive ventilation.¹⁵ Mechanical ventilation has been associated with atelectasis and cardiac, infectious, and veno-occlusive complications.⁸ MG patients requiring mechanical ventilation have high mortality rates of 4% to 17%, with common causes of death identified as acute respiratory distress syndrome, disseminated intravascular coagulation, cardiac failure, and multiorgan failure.⁶ Duration of mechanical

ventilation usually ranges from 1 to 4 weeks. Age more than 50 years, preintubation serum bicarbonate level of 30 mmol/L or more, and peak VC less than 25 mL/kg in the first week after intubation were noted to be the three independent predictors of prolonged intubation.⁷ Major medical complications secondary to myasthenic crisis are related to days on mechanical ventilation. Fever is the most common complication (occurring in 70% of patients), followed by pneumonia (in 50%) and atelectasis (in 40%). Half of those who survive an MG crisis are functionally dependent at discharge, more commonly with intubation period more than 2 weeks.⁷

GUILLAIN-BARRÉ SYNDROME

Mechanical ventilation is required in 20% to 30% of patients with GBS.^{22,23} A majority of complications in GBS occur during this stage. The decision of when to intubate GBS patients with respiratory failure has been discretionary. It requires a clinical choice between premature intubation with possible secondary risk of tracheal and pulmonary injury or watchful observation, which could lead to the need for emergency intubation. GBS patients requiring emergency intubation had prolonged mechanical ventilation and anoxic brain injury if associated with respiratory arrest.²⁴

Several clinical factors have been proposed to predict when to intervene. Predictive factors for intubation include rapid progression, dysautonomia, bilateral facial palsy, and oropharyngeal weakness.²⁵ Serial measurements on pulmonary function testing are essential in anticipating the need for mechanical ventilation. As previously mentioned, the 20/30/40 rule may help to predict the need for mechanical ventilation.⁵ Profound abnormalities of phrenic nerve conduction time and findings on diaphragmatic electromyography may predict the need for mechanical ventilation.²⁶

Duration of mechanical ventilation in patients with GBS ranges from 18 to 49 days.²⁷⁻²⁹ Inspiratory pressures and ABG tests immediately preceding intubation do not predict the need for prolonged ventilation.^{23,29} IVIG and plasma exchange have been shown to reduce the duration of ventilation in randomized trials.³⁰ Prolonged intubation (14 days) was found to be associated with increased morbidity and mortality rates, mainly due to increased risk of ventilator-associated pneumonia and longer duration of mechanical ventilation.³¹ Mechanical ventilation-related respiratory complications such as pneumonia and tracheobronchitis occur in more than half of GBS patients. An increase in ICU stay also increased the number of systemic infections.¹⁰ Complications are less common if the ICU stay is less than 3 weeks. Independent ambulation can be seen in up to 80% of patients who survive from the acute phase of GBS.¹⁰ Patients may take 2 months to 10 years for independent ambulation.³² ICU complications, prolonged mechanical ventilation, and early axonal abnormalities are associated with slower recovery.⁷ Advanced age and delay in transfer to ICU are independent factors predictive of poor outcome.³³

Aggressive respiratory therapy, including frequent suctioning and use of ventilatory strategies aiming at minimizing atelectasis, should be emphasized. If no improvement is noted, aggressive respiratory management should include tracheostomy to allow more efficient bronchial clearing and reduction in the work of breathing imposed by the

endotracheal tube. Tracheostomy and its timing are debated topics. The need for tracheostomy is more likely in the elderly and in the presence of preexisting pulmonary disease.²³ A majority of patients with GBS-associated neuromuscular failure and mechanical ventilation undergo tracheostomy (up to 89%).³¹ Tracheostomy should be postponed until the third week in patients who show some clinical improvement. This provides a period of assessment during which neuromuscular respiratory function may improve in response to treatment, and up to 50% of these patients (those showing improvement) could be spared from tracheostomy by waiting until the third week.

Percutaneous tracheostomy may allow transfer of unstable patients to the operating room, thereby decreasing the incidence of wound infection, reducing cost, and providing better cosmetic results. Tracheostomy-related complications include short-term complications such as bleeding from the tracheostomy site, early cuff leak, wound infection, wound breakdown, and self-decannulation; long-term complications include minor voice change.³⁴ Percutaneous tracheostomy decreases the incidence of complications such as tracheal obstruction and pneumothorax, which are seen more often in open tracheostomy.³⁵ With the current neurocritical care availability for GBS patients, the mortality rate has decreased to less than 5%.^{32,33}

EXTUBATION TRIALS

Weaning from mechanical ventilation should be guided by improvement in strength and normalization of values on serial pulmonary function tests. Diaphragmatic weakness may reverse before extremity weakness; thus, the timing of weaning should not be gauged solely by recovery of extremity muscle strength.

The weaning process in patients with MG often is challenging because of the fluctuating nature of the disease. Reintubation is not uncommon. In a review of 26 episodes of myasthenic crisis, the reintubation rate was 27%. In selected patients, noninvasive ventilation can be used for bridging during the weaning process to prevent reintubation.³⁶ Older age, pneumonia, and atelectasis are major risk factors for poor outcome.³⁷ Weaning trials may begin when VC exceeds 15 mL/kg, P_{max} exceeds −30 cm H₂O, and oxygenation is adequate on inspired oxygen concentrations (F_{IO₂}) of 40% or less. It is important to reintroduce cholinesterase inhibitors before extubation trials are initiated. Weaning methods may vary. Patients can be switched to continuous positive airway pressure (CPAP) with pressure support ventilation (PSV) and the level decreased 1 to 3 cm H₂O each day. A decrease in tidal volume and an increase in respiratory and heart rates are indicators of fatigue. Once the patient demonstrates good endurance at low pressure support (5 cm H₂O), usually for more than 2 hours, extubation can be accomplished. After extubation, incentive spirometry is helpful to reduce the risk of atelectasis and reintubation.³⁸

In GBS, weaning from mechanical ventilation should be undertaken as early as possible because of the number of significant complications related to prolonged intubation.³⁹ After intubation, however, respiratory function parameters often continue to fall. Reducing intermittent mandatory ventilation rate or reducing pressure support level can be

used as weaning approaches, at the discretion of the treating physician. However, one should anticipate weeks on the ventilator. The weaning process can be initiated once VC reaches 25 mL/kg and spontaneous tidal volumes of 10 to 12 mL/kg are attained. P_{max} exceeding −50 cm H₂O and VC improvement by 4 mL/kg from preintubation to pre-extubation are associated with successful extubation.⁴⁰ Extubation often is delayed if dysautonomia is still present. Electrophysiologic testing can be helpful while deciding for extubation. Established risk factors for poor outcome in GBS are electrophysiologic evidence of axonal degeneration, preceding diarrheal illness, and rapid disease progression.²⁹

MANAGEMENT

MYASTHENIA GRAVIS

Treatment of MG is geared toward identifying the typical causes of crisis (Fig. 64.4). Common causes of myasthenic crisis as mentioned earlier include infection, aspiration, surgery (especially thymectomy), and changes in medication. A careful review of medications, including over-the-counter preparations, is needed. Postoperative complications may be reduced in MG patients with baseline minimal bulbar or respiratory muscle weakness by preoperative plasma exchange or IVIG.²

The issue of cholinergic crisis is controversial. Cholinergic crisis is believed to occur as a result of overtreatment with acetylcholinesterase inhibitors. It may manifest with copious respiratory secretions and fasciculations from nicotinic toxicity. Historically, when the treatment of MG was limited to use of acetylcholinesterase inhibitors, overdose could lead to MG crisis, but this entity is now infrequently encountered, and its importance may have been overstated.⁴¹ In a retrospective review of 73 episodes of myasthenic crisis, no instances of cholinergic crisis were identified.⁷ In another review of 27 patients, only one patient had cholinergic crisis.⁶ To avoid any confusion during the acute management of myasthenic crisis, it is recommended to discontinue acetylcholinesterase inhibitors during invasive mechanical ventilation. During NMV, this decision should be made on a case-by-case basis, depending on the patient's response to acetylcholinesterase inhibitors.

The mainstay of immunotherapy for the short-term treatment of myasthenic crisis is plasma exchange. Plasma exchange directly removes AChR antibodies from the circulation, and clinical improvement roughly correlates with the degree of elimination as reflected in AChR antibody levels. Although widely used and considered effective, plasmapheresis for MG crisis has not been compared with sham exchange in a controlled trial. A total of 5 to 7 exchanges typically are done over 2 weeks, and 2 to 4 L of plasma is removed with each exchange. One randomized controlled trial did not show any difference in efficacy when plasma exchange was done daily versus every other day.⁴² Improvement usually is noted within days and can be quite dramatic, although some patients may not show evidence of response until weeks after therapy. The effects of plasma exchange may last up to 3 months. Major complications of plasma

exchange are problems with vascular access (including infection, local thrombosis, and vascular perforation), hypotension, transient electrolyte disturbances, and heparin-induced thrombocytopenia.

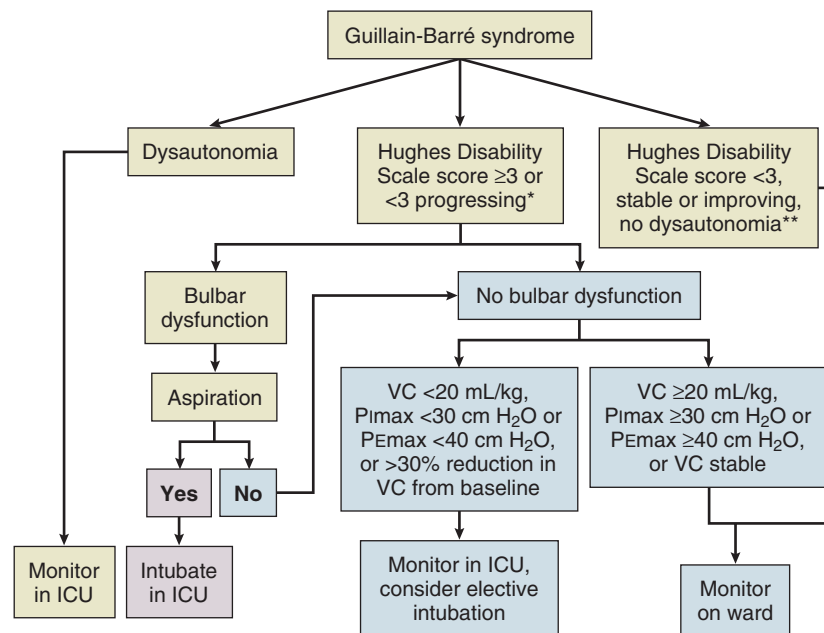

IVIG is also used in the management of MG but much less in myasthenic crisis. Its mechanism of action in MG is less certain, but it is believed to work by introduction of anti-idiotypic antibodies and reduced AChR antibody production achieved through negative feedback. IVIG when compared to placebo clearly showed benefit for MG patients in a randomized controlled trial.⁴³ It often is employed in a dose of 0.4 g/kg of body weight given over 5 days (total dose of 2 g/kg), although a recent randomized clinical trial found no significant superiority of 2 g/kg over 1 g/kg of IVIG in MG exacerbation.⁴⁴ IVIG is better tolerated as compared to a plasma exchange. Side effects related to IVIG treatment are often mild and include headache, chills, fever, and nausea. These manifestations are related to the rate of infusion. Major side effects, independent of infusion rate, are acute renal failure, thrombotic events, and anaphylaxis.

A recent randomized controlled trial comparing IVIG and plasma exchange found both therapies to be equally efficacious in MG patients, but it did not include severely affected MG patients or patients in myasthenic crisis.⁴⁵ Trials comparing plasma exchange and IVIG found more rapid onset of improvement in clinical measures of MG, as well as earlier time to extubation, with early (in the first 2 weeks) institution of plasmapheresis, but did not find any significant difference on long-term follow-up evaluation.^{46,47} One study found plasma exchange also to be effective in patients in whom IVIG has failed.⁴⁸ Plasma exchange is generally preferred as first-line therapy in MG crisis. High-dose corticosteroids can transiently worsen the neuromuscular

weakness associated with MG during early stages of treatment in up to 50% of patients. For this reason, during myasthenic crisis, it is recommended to start steroids only after initiation of plasma exchange or IVIG treatments and then to continue until a remission occurs.¹⁷

Complete thymectomy is indicated in cases of thymoma-associated MG. Thymectomy is controversial in patients without thymoma. In a 17-year follow-up study of 110 MG patients, post-thymectomy myasthenic crisis episodes were fewer, were less severe, required less ventilatory support, and had reduced ICU stay when compared to a nonsurgical group.⁴⁹ Desflurane plus remifentanyl was found to be a better anesthetic combination than propofol plus remifentanyl in MG patients undergoing video-assisted thoracoscopic-extended thymectomy due to its reversible muscle relaxation effect and faster recovery with no increase in side effects.⁵⁰ Empiric thymectomy in the elderly is likely to be less effective because of atrophy of the thymus.

Post-thymectomy myasthenic crisis is not uncommon and can be seen in up to 30% of patients. Most of these patients (65%) present within the first 6 months.⁵¹ Alternate day oral corticosteroids reduce immediate postoperative myasthenic crisis to 5% based on a retrospective series.⁵² Plasma exchange and IVIG can also be useful to prevent deterioration preoperatively in patients undergoing thymectomy or other surgery. Preoperative plasma exchange was found to reduce the incidence of postoperative myasthenic crisis and improve long-term outcome.⁵³ In a retrospective study, predictors of postoperative myasthenic crisis were preoperative oropharyngeal weakness, preoperative serum anti-AChR antibody level greater than 100 nmol/L, and intraoperative blood loss greater than 1 L.⁵⁴ Previous history of myasthenic crisis and presence of thymoma are other significant predictors for post-thymectomy myasthenic crisis.⁵⁵ Delaying

* Indicates that the patient is able to walk unassisted more than 5 m.

** Indicates that the patient is unable to walk unassisted more than 5 m or is bedridden or mechanically ventilated.

thymectomy until immunosuppressive treatment has been initiated and bulbar symptoms are resolved may be beneficial in avoiding postoperative myasthenic crisis. Postoperative myasthenic crisis leads to prolonged mechanical ventilation and need for tracheostomy. Improvement after thymectomy may not be seen for months or even years.

GUILLAIN-BARRÉ SYNDROME

The management of patients with GBS can be challenging because of its unpredictable course, potential for rapid deterioration, and high chances for respiratory failure (Fig. 64.5). Any patient with worsening weakness on initial evaluation or presentation will need admission and observation in an ICU. However, only 1 in 3 patients will deteriorate significantly enough to mandate further or prolonged ICU monitoring and possibly intubation.

Main modalities of acute treatment are plasma exchange or IVIG, both of which are recommended for nonambulatory patients with GBS who present within 4 weeks of disease onset. Large multicenter trials have established the effectiveness of plasma exchange in GBS.^{56,57} Earlier clinical improvement, reduced need for mechanical ventilation, and faster recovery have been shown with plasma exchange. A systematic review of six randomized trials in 2002 found that plasma exchange was superior to supportive care.⁵⁸ Plasma exchange was most effective when started within 7 days of symptom onset; however, an improvement in outcome was still observed if treatment was instituted up to 30 days after onset of symptoms in the North American study. Two plasma exchanges are superior to none in mild GBS, and four exchanges are superior to two in moderately severe GBS. However, six exchanges were not superior to four in severe GBS requiring mechanical ventilation.⁵⁹

No randomized trials have been conducted to compare IVIG with placebo for the treatment of GBS, but IVIG was shown to be as effective as plasma exchange for the treatment of GBS by a Cochrane systematic review of five trials.⁶⁰ Analysis found no significant difference between plasma exchange and IVIG in disability scores at 4 weeks; however, treatment effect was faster with plasma exchange as compared to IVIG.⁴⁶ Combining IVIG with plasma exchange also has been tried and was found not to have additional benefit.⁶¹ Corticosteroids alone have no significant benefit in GBS. Intravenous methylprednisolone in combination with IVIG may hasten recovery but does not significantly affect the long-term outcome or neuropathic pain from GBS.^{62,63} One third of the patients felt completely cured at 12 months, changed their job due to GBS, and did not function at home as well as before in a self-administered questionnaire containing questions on their physical status at homecoming and at 12 months.⁶⁴

KEY POINTS

- Clinical examination and pulmonary function tests form the basis of assessment in patients with neuromuscular respiratory failure.
- VC less than 20 mL/kg, PImax less than 30 cm H₂O, and PEmax less than 40 cm H₂O usually will indicate the need for mechanical ventilation in patients with GBS (20/30/40 rule).
- In myasthenic crisis, pulmonary function tests have a limited positive predictive value. Respiratory support

KEY POINTS (Continued)

- is unlikely to be needed when VC is more than 20 mL/kg.
- NMV is the first-line treatment in respiratory failure secondary to MG when PCO₂ level is less than 45 mm Hg and definitive therapy is rapidly initiated. This can prevent intubation up to 60% of the time.
- NMV is not beneficial in respiratory failure secondary to GBS and can even be detrimental by masking further respiratory decline.
- Timing for tracheostomy in GBS is unclear, but waiting for 2 to 3 weeks in patients showing improvement may prevent the need for tracheostomy in up to 50% of cases.
- Both IVIG and plasma exchange probably are equal in efficacy for the treatment of GBS.
- In treatment of ventilatory failure secondary to MG, plasma exchange is superior to use of IVIG. Plasma exchange or IVIG must be followed by long-term immunosuppression.

Status Epilepticus

Controversial Management Issues

PROGNOSIS

Seizures complicate the course of about 3% of adult patients admitted to intensive care units (ICUs) for non-neurologic conditions¹ and occur more frequently in specialized neuroscience ICUs.² The medical and economic impact of seizures in these patients confers a significance on these events out of proportion to their incidence. Seizures are often the first indication of a central nervous system (CNS) complication in these patients, making their rapid etiologic diagnosis mandatory. Furthermore, because epilepsy is a common disorder (affecting about 2% of the general population), patients with preexisting seizure disorders will occasionally require ICU admission for intercurrent conditions. The intensivist usually manages the initial treatment of these patients, so he or she must be familiar with the indications and risks of the potential therapies as they affect the already critically ill patient. In addition, the patient who develops status epilepticus (SE), whether already in the ICU or not, will often require the care of a critical care specialist in addition to a neurologist.

HISTORY

Although seizures have been recognized at least since Hippocratic times, their relatively high rate of occurrence in critically ill patients has only recently been recognized. Seizures as a side effect of critical care treatments (e.g., as a complication of lidocaine infusion for ventricular arrhythmias) are also a recent phenomenon.

The first recorded description of SE is by Gavasetti in 1586.^{3,4} Sir Thomas Willis described the complications of untreated SE in 1667:

... as to what further belongs to the prognostication of the Disease, if it end not about the time of ripe age, neither can be driven away by the use of medicines, there happens yet a diverse event in several sick Patients, for it either ends immediately in Death, or is changed into some other Disease, to wit, the Palsie, stupidite, or melancholly, for the most part incurable. As to the former, whenas the fits are often repeated, and every time grow more cruell, the animal functions are quickly debilitated; and from thence, by the taint, by degrees brought on by the Spirits, and the Nerves serving the Praecordia, the vital function is by little and little enervated, till at length, the whole body languishing, and the pulse is loosened, and at length ceasing, at last the vital flame is extinguished.⁵

Attempts at treating SE in the nineteenth century included bromide,⁶ morphine,⁷ and ice applications. Barbiturates were introduced in 1912, followed by the identification and use of phenytoin in 1937; these were the first rational treatments for SE.⁸ Paraldehyde gained brief prominence in the next decades.⁹ The most recent major improvement is the use of benzodiazepines, pioneered by the French in the 1960s.¹⁰

EPIDEMIOLOGY

Few data are available concerning the epidemiology of seizures in ICU patients. A 10-year retrospective study of all ICU patients at the Mayo Clinic reported approximately 7 patients with seizures per 1000 ICU admissions.¹¹ In a 2-year prospective study of a medical ICU, we acquired approximately 35 patients with seizures per 1000 admissions.¹ These

*Conditions most likely to result in admission to intensive care unit (ICU).

analyses are not strictly comparable, because the patient populations and methods of detection differed. The incidence of seizures is probably higher in pediatric ICUs than in medical ICUs.¹²⁻¹⁴

Certain ICU patients appear to be at increased risk for seizures, but the degree of that increased risk has not been quantified. Patients with renal failure or with an altered blood-brain barrier who receive imipenem-cilastatin are an obvious example, but other patients receiving this antibiotic (or γ -aminobutyric acid [GABA] antagonists such as penicillin) occasionally seize. Cefepime has emerged as a cause of nonconvulsive seizures and SE, especially in patients with renal insufficiency.¹⁵ Transplant patients, especially those receiving cyclosporine, appear to have an increased risk for convulsions. Patients who rapidly become hypo-osmolar from any cause are also at risk. Nonketotic hyperglycemia patients have a high likelihood of partial seizures; this is a rare instance of a metabolic disorder producing focal neurologic syndromes.¹⁶ Less commonly, diabetic ketoacidosis may also produce partial seizures.¹⁷

The epidemiology of SE is somewhat better understood. Estimates of the incidence of generalized convulsive SE in the United States range from 50,000 cases/year¹⁸ to 250,000 cases/year.¹⁹ Some portion of this discrepancy may be due to differences in definitions. The larger estimate comes from the only population-based data available and may be more accurate. Similarly large variations occur in mortality rate estimates, from 1% to 2% in the former study to 22% in the latter. This disagreement stems, at least in part, from a conceptual discordance: the smaller number attempts to determine mortality rate that the authors directly attribute to SE, while the larger figure reflects the overall mortality rate for SE patients, in whom death was frequently a consequence of the cause of the underlying disease rather than SE itself. In the latter study, for example, anoxia was the cause of SE in adults with the highest mortality rate. In many of the reports surveyed in the earlier review, these patients were not included.

A number of important risk factors have emerged from the Richmond study. When SE lasted longer than 1 hour, the mortality rate was 32%; when it lasted less than 1 hour, the mortality rate was only 2.7%. SE caused by anoxia was associated with a mortality rate of about 70% in adults, but the corresponding rate in children was less than 10%. After the age of 12 months, the mortality rate of SE rose with increasing age. In their study, the commonest cause of SE in adults was stroke, followed thereafter by withdrawal from anticonvulsant drug therapy; cryptogenic (or idiopathic) SE; and SE related to ethanol withdrawal, anoxia, and metabolic disorders. Systemic infection was the most commonly diagnosed cause of SE in children; this was followed by congenital abnormalities, anoxia, metabolic disorders, anticonvulsant drug withdrawal, CNS infections, and trauma. Although brain tumors seldom caused SE in children, such patients experienced a nearly 50% mortality rate.

Towne and colleagues demonstrated that 8% of an unselected series of comatose medical ICU patients had unsuspected nonconvulsive status epilepticus (NCSE).²⁰ In septic ICU patients, Oddo and colleagues showed that about 30% have periodic epileptiform activity or NCSE when recorded for 24 hours or longer.²¹

Hospital-based series of SE patients are usually subject to considerable selection bias regarding cause. The data in Table 65.1, based upon 20 years of experience in San Francisco, are of great interest because almost all patients with SE in the city of San Francisco who began to seize outside the hospital are included.²²⁻²⁴

Between 6% and 12% of epilepsy patients present with SE,²⁵ and about 20% of seizure patients will experience an episode of SE within 5 years of their first seizure.¹¹

NOSOLOGY AND SEMIOLOGY

Numerous systems have evolved for the classification of seizures; the most frequently used today is that of the

Box 65.1 International Classification of Epileptic Seizures

- I. Partial seizures (seizures beginning locally)
 - A. Simple partial seizures (consciousness not impaired) (SPS)
 1. With motor symptoms
 2. With somatosensory or special sensory symptoms
 3. With autonomic symptoms
 4. With psychic symptoms
 - B. Complex partial seizures (with impairment of consciousness) (CPS)
 1. Beginning as SPS and progressing to impairment of consciousness
 - a. Without automatisms
 - b. With automatisms
 2. With impairment of consciousness at onset
 - a. With no other features
 - b. With features of SPS
 - c. With automatisms
 - C. Partial seizures (simple or complex), secondarily generalized
- II. Primary generalized seizures (bilaterally symmetric, without localized onset)
 - A. Absence seizures
 1. True absence ("petit mal")
 2. Atypical absence
 - B. Myoclonic seizures
 - C. Clonic seizures
 - D. Tonic seizures
 - E. Tonic-clonic seizures ("grand mal") (generalized tonic-clonic [GTC])
 - F. Atonic seizures
- III. Unclassified seizures

From Commission on Classification and Terminology of the International League Against Epilepsy: Proposal for revised clinical and electroencephalographic classification of epileptic seizures. *Epilepsia* 1981;22:489-501.

International League Against Epilepsy²⁶ (Box 65.1). This schema allows classification based primarily on clinical criteria, without inferences about cause. Although a more recent proposal for terminology has been published, it is not yet widely accepted.²⁷ It is important because of its predictive value for cause, prognosis, and treatment decisions in ICU patients. *Simple partial* seizures arise focally in the cerebral cortex, without taking over either the limbic system or subcortical nuclei. The patient remains aware of the environment during the ictus, and except for the seizure itself appears unchanged. Bilateral limbic system dysfunction results in a *complex partial* seizure; the patient's awareness and ability to interact with the environment are diminished (but not always completely abolished). *Automatisms* are movements that the patient seems to make without being aware of them; typical automatisms include swallowing, masticatory movements, and fumbling with nearby items. *Secondary generalization* implies invasion of either the other hemisphere (with loss of consciousness) or, more commonly, subcortical structures, with the development of a generalized convulsion.

Primary generalized seizures seem to arise from the entire cerebral cortex and the diencephalon at the same time; there are no visible focal phenomena. Consciousness is lost

from the start of the seizure. True *absence* seizures are usually confined to childhood; they consist of the abrupt onset of a blank stare usually lasting 5 to 15 seconds, without lateralizing phenomena, from which the patient abruptly returns to normal. Atypical absence is usually seen in children who have the Lennox-Gastaut syndrome. *Myoclonic* seizures begin with brief, bilaterally synchronous jerks without an initial change in consciousness, followed by a generalized convulsion. They occur in several of the genetic epilepsies, but in the ICU are more commonly the consequences of anoxia or metabolic disturbances.²⁸ *Clonic* seizures involve repetitive movements; they may be generalized (synchronous movements of all extremities and both sides of the face) or partial (e.g., one side of the face and the arm of the same side). *Tonic* seizures are episodes of tonic extension of the arms, legs, and trunk; they must be distinguished from decerebrate rigidity and from tetanic spasms.²⁹ *Tonic-clonic* seizures begin with tonic extension, followed by a brief phase of rapid vibration of the extremities, evolving into bilaterally synchronous clonus, and concluding with a post-ictal phase in which incontinence is common and brief apnea is occasionally noted. They may be primarily generalized or, more commonly, occur as the manifestation of spread of a partial seizure. Only those seizures that are known to involve progression through the tonic and clonic stages should be called tonic-clonic.

When seizures occur in ICU patients, clinical judgment is required to apply this system. Patients whose consciousness is already altered by drugs, hypotension, sepsis, or intracranial disease may be difficult to diagnose regarding the "simple" or "complex" nature of their partial seizures.

SE is classified by a somewhat similar system, with alterations to match the observable clinical phenomena (Box 65.2).³⁰ Again, the ability to use clinical observation without inferences about cause is important. *Generalized convulsive SE* (GCSE) is the type most commonly encountered in ICUs, and poses the greatest risk to the patient. GCSE may be either primarily generalized, as in the intoxicated patient, or may represent secondary generalization, as in the patient with a brain abscess who develops GCSE. *Tonic SE* is usually seen in children or adolescents with a history of severe CNS dysfunction. *Nonconvulsive SE* (NCSE) in the ICU is most commonly the consequence of partially treated GCSE. Some authors use this as a general term for any SE involving altered consciousness without convulsive movements. Although conceptually useful, this blurs the distinctions among absence SE, partially treated GCSE, and *complex partial SE* (CPSE), which have different causes and treatments. *Epilepsia partialis continua* (EPC) is a special form of partial SE in which a small area of the body makes repetitive movements, sometimes for months or years following a CNS insult.

PATHOGENESIS

Clinical SE has a large variety of causes. The relative frequencies of causes depend upon the definition of SE employed (e.g., if repetitive, stereotyped myoclonic activity after a cardiorespiratory arrest is considered SE, then the frequency of such arrests as a cause of SE will rise).

The reported "causes" of SE can be separated, if imperfectly, into predispositions and precipitants. *Predispositions*

are relatively fixed conditions that increase the likelihood of SE, such as a brain tumor, in the presence of a precipitant. *Precipitants*, in contrast, are transient conditions that can produce SE in most, if not all, people but will tend to affect those with predispositions at lesser degrees of severity (e.g., barbiturate withdrawal).

For experimental purposes, the nosologic division of SE into partial (focal) or generalized based on the type of seizure produced works well, as does the recognition of convulsive and nonconvulsive seizure types. One must recognize that these are models of *acute SE*; they are not chronic conditions that occasionally produce SE, as are many of the afflictions of patients. Nevertheless, they have substantial explanatory power for understanding the neuronal and systemic processes of SE, for studying its consequences, and for predicting responses to therapy.

PATHOPHYSIOLOGY

The causes and effects of SE at the cellular, brain, and systemic levels are interrelated, but their individual analysis is useful for understanding them and their therapeutic implications. One must first understand the consequences of a single seizure and then contrast this information with the effects of prolonged or frequent seizures merging into SE. Longer durations of SE produce more profound alterations with an increasing likelihood of permanence, and of becoming refractory to treatment. [Figure 65.1](#) illustrates the variety of processes involved in a single seizure and in the transition to SE.³¹

The ionic events of a seizure follow the opening of ion channels coupled to excitatory amino acid (EAA) receptors. Although the endogenous ligands of these channels are glutamate and aspartate, the channels are named for synthetic compounds that potently activate them. From the standpoint of the intensivist concerned with SE, three channels are particularly important because their activation may raise intracellular free calcium to toxic concentrations. The first channels primarily conduct sodium ions (the AMPA [amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid] channels). The second are the *N*-methyl-D-aspartate (NMDA) channels, which admit sodium and calcium when the cell has been depolarized (which relieves the resting blockade of the ionophore by magnesium). The third, the metabotropic or ACPD (aminocyclopentane-trans-1,3-dicarboxylic acid) channels, mobilize calcium from intracellular stores via coupling to G-protein-linked second messengers.

These EAA systems are normally crucial for learning and memory. Many drugs that block these systems, such as ketamine, are too toxic to use as chronic anticonvulsants. However, the deleterious consequences of SE, and the brief period during which they would be needed, suggest that similar agents may prove to have a role in the management of SE. Counterregulatory ionic events are also triggered by the epileptiform discharge; the most important is activation of inhibitory interneurons, which feed back to the bursting cells via GABA_A synapses.

The cellular consequences of the excessive EAA channel activation include (1) accumulation of toxic concentrations of free intracellular calcium; (2) activation of autolytic enzyme systems; (3) production of oxygen-derived free radicals; (4) generation of nitric oxide, which both enhances subsequent excitation and serves as a toxin; (5) phosphorylation of several enzyme and receptor systems, making seizures likely; and (6) increasing intracellular osmolality, thereby producing neuronal swelling. If adenosine triphosphate (ATP) production should fail (because the substrate becomes inadequate or is diverted into EAA-related events), membrane ion exchange systems stop functioning, and the neuron swells further. These events are responsible for the neuronal damage associated with SE.

Many other important biophysical and biochemical alterations occur during and after SE. The intense neuronal activity activates immediate-early genes and produces heat shock proteins, providing strong indications of the deleterious effects of SE and insight into the mechanisms by which neurons protect themselves.³² Wasterlain's group summarized the many mechanisms through which SE damages the nervous system.³³

Absence SE is an exception among these conditions. It appears to consist of rhythmically increased inhibition and does not produce clinical sequelae or neuropathologic abnormalities.

The mechanisms that terminate seizure activity are uncertain. Given the relative rarity of SE in a population in which at least 1 in 50 patients has had a seizure, one must infer that these mechanisms are generally effective. The leading candidates for seizure terminating systems are inhibitory mechanisms, primarily GABAergic neuronal aggregates. This hypothesis receives strong support from the clinical observation that human SE frequently follows withdrawal from GABA agonists (e.g., benzodiazepines).

Figure 65.1 Pathophysiology of status epilepticus (SE). Summary of pathophysiologic events during experimental SE. Note that the abscissa is discontinuous. Numerals in figure indicate the following events: 1, loss of cortical responsiveness to changes in oxygen tension; 2, a fall in cerebral blood flow; 3, depletion of brain glucose; and 4, a decline in the total brain energy state. (Adapted from Lothman EW, Bertram EH: Epileptogenic effects of status epilepticus. *Epilepsia* 1993;34[Suppl 1]:S59-S70.)

Table 65.2 Electrographic-Clinical Correlations in Generalized Convulsive Status Epilepticus

Stage	Typical Clinical Manifestations*	Electroencephalographic Features
1	Tonic-clonic convulsions; hypertension and hyperglycemia common	Discrete seizures with interictal slowing
2	Low- or medium-amplitude clonic activity, with rare convulsions	Waxing and waning of ictal discharges
3	Slight, but frequent, clonic activity, often confined to the eyes, face, or hands	Continuous ictal discharges
4	Rare episodes of slight clonic activity; hypotension and hypoglycemia become manifest	Continuous ictal discharges punctuated by flat periods
5	Coma without other manifestations of seizure activity	Periodic epileptiform discharges on a flat background

*The clinical manifestations may vary considerably, depending on the underlying neuropathophysiologic process (and its anatomy), systemic diseases, and medications. In particular, stages of the electrographic progression may be sufficiently brief to be overlooked. Partially treating status epilepticus may dissociate the clinical and electrographic features.

The electrical phenomena of SE at the whole brain level, as seen in the scalp electroencephalogram (EEG), reflect the seizure type that initiates SE (Fig. 65.2). Thus, absence SE begins with a generalized 3-Hz wave-and-spike EEG pattern. During the course of SE, there will usually be some slowing of this rhythm, but the wave-and-spike characteristic persists. In contrast, GCSE goes through the sequence of EEG changes outlined in Table 65.2. The initial high-frequency discharge becomes progressively less well formed over minutes; this pattern implies that neuronal activity is less synchronous. Whether this indicates that inhibitory systems are attempting to terminate SE, a progressive decay in the ability of synaptic mechanisms to maintain synchrony,

or global deterioration in neuronal function remains to be determined.

The repetitive firing that characterizes SE alters the extracellular microenvironment. The most important change is probably the elevation of the extracellular potassium concentration. Although extruding potassium is an effective strategy to maintain normal electronegativity, the excessive amounts of potassium ejected during SE overcome the ability of astrocytes to buffer it. Patients with cerebral edema, glial scarring, or alien tissue lesions have extracellular space abnormalities that impair the potassium buffering ability of glial cells. Raising extracellular potassium is a potent epileptogenic stimulus.

Figure 65.2 Electroencephalographic recording during status epilepticus. The first panel illustrates the onset of the seizure; the subsequent panels show its evolution. Montage: longitudinal bipolar; channels 1 to 4, left temporal; and channels 5 to 8, left parasagittal. Calibration: vertical, 50 μ v; horizontal, 1 second.

The tremendously increased cellular activity of SE elevates tissue demand for oxygen and glucose. To meet this demand, cerebral blood flow initially increases threefold or greater. However, after about 20 minutes, energy supplies become exhausted. This accentuates the demand for local catabolism in order to support ion pumps (in a vain attempt to restore the internal milieu during the flood of sodium and calcium). Many researchers believe that this is the major cause of epileptic brain damage in GCSE. Other forms of SE may not be subject to such severe hypercatabolism, but still pose a risk.

When partial seizures generalize, subcortical structures begin to play an active role in the clinical phenomena

observed. Spread of the electrical activity into the substantia nigra and other subcortical regions appears to be necessary before a tonic-clonic convulsion occurs.

The brain contains intrinsic systems that terminate seizure activity; both local GABAergic interneurons and inhibitory thalamic neurons are involved. Whether these systems have evolved, at least in part, for protection against seizures, or whether this effect is an epiphenomenon of some other physiologic function, is unresolved.

SE can produce cerebral edema, which follows ictal damage to the blood-brain barrier.

Prolonged SE produces chronic neuropathologic changes. Prior to the 1970s, these changes were often attributed

Figure 65.2, cont'd

to the systemic effects of SE (e.g., hypoxia and hyperthermia). However, SE itself produces these changes even in patients who are paralyzed, ventilated, and maintained at normal temperature and blood pressure. The hippocampus, which is one of the most important areas for memory function, contains the most susceptible neurons, but the cerebral cortex is also vulnerable. These regions express high densities of EAA receptors, and may be relatively deficient in systems for handling unusual elevations of free intracellular calcium. Cells that contain nitric oxide synthase seem relatively protected.

In addition to damaging the CNS, GCSE produces serious, often life-threatening, systemic effects.³⁴ Pressures in the systemic arterial system (under sympathetic control) and in the pulmonary arterial system (raised via efferents from

pontine and medullary centers) are dramatically elevated from the moment of seizure onset. Epinephrine and cortisol release prompts further elevations of systemic arterial pressure, and also produces hyperglycemia. Increased muscular work raises the circulating lactate concentration. Respiration becomes ineffective; both airway obstruction and diaphragmatic contraction impede air movement. The consequent hypoxia further elevates lactate levels. Ventilatory failure impairs CO₂ excretion while CO₂ production increases markedly, adding a respiratory component to the acidosis. In GCSE, the arterial blood pH frequently falls below 7.0. The muscular work accelerates heat production; when coupled with decreased dermal blood flow (produced by sympathetic stimulation), GCSE can quickly raise the core temperature to 40° C or higher.

If GCSE is not completely controlled within the first 20 minutes, motor activity begins to diminish in intensity, and ventilation usually improves. Therefore, even without treatment, the metabolic acidosis improves. Core temperature may continue to climb, however, probably reflecting hypothalamic dysfunction. The initial hyperglycemia diminishes; after an hour or more, hepatic gluconeogenesis may fail, and hypoglycemia develops.

GCSE patients frequently suffer secondary complications as well. Aspiration of oral or gastric contents commonly produces chemical pneumonitis, with bacterial pneumonia often following. Rhabdomyolysis is common, and is occasionally followed by acute renal failure. Compression fractures, joint dislocations, and tendon avulsions are other common sequelae of GCSE.

CLINICAL MANIFESTATIONS

RECOGNITION OF SEIZURES

Because of the close observation patients receive in the critical care setting, most seizures are witnessed. The partial onset of a secondarily generalized convulsion, a finding of important diagnostic significance, is more likely to be seen and properly described in the ICU than on regular hospital floors or in the community. Three problems occur in ICU seizure recognition: (1) complex partial seizures in patients with already impaired awareness, (2) seizures in patients receiving neuromuscular junction blockade, and (3) the misinterpretation of movement disorders and psychiatric disturbances as seizures. (In any ICU patient who develops abnormal movements or unexplained changes in awareness, thiamine deficiency should be excluded immediately by giving thiamine.)

ICU patients often have altered awareness in the absence of seizures, reflecting their underlying condition, complications of those conditions (such as septic encephalopathy³⁵), and drugs that depress alertness (intentionally or not). Although clonic motor activity in these patients remains visible, it may be difficult to tell whether a subsequent further decline in alertness reflects a seizure or some other process. In this situation, an EEG is required to make the diagnosis of a complex partial seizure. Although the detailed interpretation of EEGs is beyond the scope of this chapter, the intensivist can easily learn to recognize basic seizure types and other important EEG abnormalities in critically ill patients.³⁶

Patients receiving neuromuscular junction blocking agents will not manifest any of the usual signs of seizures. Because most such patients receive concomitant sedation with GABA agonists (e.g., benzodiazepines), the likelihood of seizures is small. The autonomic signs of seizures (hypertension, tachycardia, pupillary dilation) are not readily distinguished from the effects of pain or the patient's response to inadequate sedation. Thus, any patient who manifests these findings and who has a potential reason for seizures (e.g., intracranial disease) should have an EEG to exclude this possibility.

Many sorts of abnormal movements occur in patients with severe metabolic disturbances or anoxic brain damage. Some of them can be distinguished from seizures by

observation; such movements are frequently evoked or exacerbated by sensory stimuli and can sometimes be suppressed by changing the patient's posture. However, Hirsch and colleagues have demonstrated that seizures in ICU patients may be induced by external stimuli³⁷; if any doubt about the nature of such movements persists, an EEG should be performed.

During therapeutic cooling for patients in a coma after cardiac arrest, seizures may be difficult to detect clinically, especially when neuromuscular junction blockade is used.³⁸ EEG monitoring should be performed.³⁹

MANIFESTATIONS OF STATUS EPILEPTICUS

The neurologic manifestations of SE depend on the type of SE and, for the partial forms, the area of cortex from which the abnormality arises. Box 65.2 summarizes the types of SE encountered in clinical practice. This section will focus on the varieties of SE seen most frequently among ICU patients.

Primary GCSE usually begins as tonic extension of the trunk and extremities, without any preceding focal ictal activity. If the patient was awake before onset, no aura is reported, and consciousness is immediately lost. After several seconds of tonic extension, the extremities begin to vibrate; this phase gives way to clonic (rhythmic) extension of the extremities, with flexion occurring during each brief relaxation. Usually, this clonic phase will wane in intensity over 1 to 3 minutes. The patient developing SE may then repeat the cycle of tonic activity followed by clonic movements, or may continue to have intermittent bursts of clonic activity without recovery between. Less commonly encountered forms of GCSE are *myoclonic SE*, in which bursts of brief myoclonic jerks increase in intensity until a convulsion occurs, and *clonic-tonic-clonic SE*, in which a period of clonic activity precedes the first tonic contraction. Myoclonic SE is particularly common in patients with anoxic encephalopathy or metabolic disturbances, particularly renal failure.

Secondarily generalized SE in the ICU begins with a partial (focal) seizure, which progresses to a tonic-clonic convulsion. Even under the watchful eye of the ICU staff, the initial focal clinical activity may be overlooked. Because this type of seizure is very strong evidence of a structural brain lesion, care should be taken to elicit evidence of any lateralized movement. *Tonic SE* is almost always confined to patients (usually children) with serious preexisting cerebral disorders. Its importance in critical care practice follows from the observation that benzodiazepines may *precipitate* tonic SE; paradoxically, these agents are also used to treat it.

There are several forms of generalized NCSE. Of greatest importance to intensivists is NCSE as a sequel of inadequately treated GCSE. In this circumstance, a patient with GCSE is treated with one or more anticonvulsants, often in inadequate doses, after which visible convulsive activity stops. However, the patient does not awaken (or otherwise return to baseline), and SE is actually continuing. As a rule, patients are expected to begin to awaken within 15 to 20 minutes after the successful termination of SE; many will regain consciousness much faster. Those who have not begun to awaken after 20 minutes should be assumed to have entered NCSE. This form of SE is sometimes termed *subtle SE*, and careful observation will often reveal low-amplitude clonic activity in some part of the body (most

commonly, the face or the hands). Most investigators view NCSE as an extremely dangerous problem, because the neuronally destructive effects of SE continue unabated, often for several hours. *This condition requires emergent treatment under EEG monitoring* to prevent further cortical damage. There are no clinical criteria, which indicate when therapy has finally become effective.

The usual form of *partial SE* in the ICU follows a stroke or is seen in patients with rapidly expanding cerebral masses (e.g., abscesses). Although clonic motor activity is the most easily recognized form, the seizure will take on the functional characteristics of the adjacent functional tissue. Thus, somatosensory or special sensory manifestations may occur; the ICU patient who is already neurologically impaired may not be able to report these symptoms. Aphasic SE may occur if the seizure begins in a language area; this must be distinguished from a stroke. Physical examination usually reveals at least some mild lateralizing findings.

EPC is a special type of partial SE in which repetitive movements are confined to a small portion of the body (typically the thumb), and may last for months or years. This type of SE is most commonly associated with nonketotic hyperosmolar hyperglycemia and does not respond to conventional anticonvulsant treatment.

CPSE presents with a state of diminished awareness, although frank loss of consciousness is rarely noted. The patient may exhibit automatisms, but commonly the diagnosis comes as a surprise when an EEG is obtained.

DIAGNOSTIC APPROACH

THE INTENSIVE CARE UNIT PATIENT WITH NEW-ONSET SEIZURES

When a patient already in an ICU has a seizure, the staff has a natural tendency to try in some way to stop the ictus. This may, unfortunately, lead to both diagnostic obscuration and iatrogenic complications. Beyond trying to protect the patient from harm, very little can be done with sufficient rapidity to influence the course of the seizure. In particular, padded tongue blades (or similar items) should not be placed in the mouth, because they are more likely to obstruct the airway than to preserve it. Similarly, most patients have stopped seizing before any medication, even administered into a preexisting intravenous line, can reach the brain in an effective concentration. A common scenario is the administration of intravenous diazepam (DZ), which begins to take effect after the seizure is over; the patient is now both postictal and pharmacologically sedated and becomes apneic.

The most important “intervention” during a single seizure is careful observation. This is the best time to collect evidence of a partial onset, which implies structural brain disease. The postictal examination is similarly valuable; language, motor, sensory, or reflex abnormalities after an apparently generalized convulsion should also be viewed as evidence of focal disease.

In addition to the standard historical information to be requested from patients and family members after a seizure, the ICU patient has several special predispositions that must be investigated. Medications are an important cause of ICU

seizures, especially in patients with diminished renal or hepatic function, or with damage to the blood-brain barrier. Imipenem-cilastatin is a common cause of seizures in this setting, but other antibiotics may also be offenders. The neurotoxic desmethyl metabolite of meperidine accumulates in renal failure; it also may produce seizures in patients with normal renal function. A complete list of potentially epileptogenic drugs is beyond the scope of this chapter; the medications of any patient who seizes should be reviewed with this possibility in mind.

Drug withdrawal is another common problem. Although ethanol withdrawal is the most common offender, discontinuing any hypnosedative agent (e.g., barbiturates, benzodiazepines, other sedatives) may prompt convulsions 24 to 96 hours later. This may be a particular problem in the ICU, where such agents may be withheld from patients because the staff is afraid that the drug’s effects will obscure the neurologic examination.

The physical examination should be conducted with special emphasis on the points mentioned earlier for the postictal examination. In addition, evidence of cardiovascular disease (as a source for cerebral emboli) and systemic infection should be sought. Careful examination of the skin and fundi are sometimes revealing. The presence of papilledema is obviously important, but its absence does exclude increased intracranial pressure.

In addition to routine biochemical studies, screening for drugs of abuse should be performed on patients with unexplained seizures. Cocaine has emerged as a prominent cause of seizures in many urban hospitals.⁴⁰ One area of controversy involves the importance of divalent cation disturbances in adult seizures. Hypocalcemia is rarely a cause of seizures beyond the neonatal period, and its discovery should not be the end of the diagnostic workup. Hyperparathyroidism has been linked anecdotally to seizures, with the inference that parathormone is neurotoxic. Similarly, hypomagnesemia has an unwarranted reputation as a cause of seizures, especially in the malnourished alcoholic patient.

In our prospective study of neurologic complications in medical ICU patients, 38 of 61 patients (62%) with seizures had a vascular, infectious, or neoplastic explanation for their fits.¹ Computed tomography (CT) or magnetic resonance imaging (MRI) should be performed on all ICU patients with new seizures, with a few exceptions. Hypoglycemia and nonketotic hyperosmolar hyperglycemia will commonly produce seizures (even partial seizures), and such patients might be treated for their metabolic disturbance and observed if there is no other indication of neurologic disease. With currently available technology, there are almost no patients who cannot be transported to undergo CT scanning. Although MRI is preferable diagnostically in most situations, the magnetic field precludes infusion pumps and other metallic devices (nonferromagnetic ventilators are available). The decision whether to administer contrast agent for a CT or MRI scan depends on the clinical setting and on the appearance of the plain scan.

The EEG is a vital diagnostic tool for the seizure patient. Partial seizures usually have EEG abnormalities, which begin in, and may remain confined to, the area of cortex producing the seizures. Primary generalized seizures, in contrast, appear to start over the entire cortex at once. Areas of postictal slowing or depressed amplitude provide clues to the

focal cause of the seizures, and interictal epileptiform activity helps to classify the type of seizure and guide the patient's subsequent treatment. In patients who do not begin to awaken soon after seizures have apparently been controlled, an emergent EEG is necessary to exclude NCSE.

The need for a lumbar puncture (LP) depends on the clinical situation. In view of the common causes of seizures in the critical care setting, those who need cerebrospinal fluid (CSF) analysis will usually require a CT scan before the LP. If a CNS infection is suspected in such patients, empiric antibiotic treatment should be strongly considered while these studies are being performed, rather than waiting for the scan to be performed and CSF results to be obtained.

THE PATIENT PRESENTING WITH OR DEVELOPING STATUS EPILEPTICUS

In contrast to the ICU patient with a single or a few seizures, the SE patient will require concomitant diagnostic and therapeutic efforts. The first issue is to make a diagnosis of SE. Because most seizures stop within 5 to 7 minutes,⁴¹ it is reasonable to begin treatment after 5 minutes of continuous seizure activity or after the second or third seizure occurring without recovery between the spells. The available treatments are discussed later.

SE has a limited differential diagnosis. GCSE might rarely be confused with decerebrate posturing, but the evolutionary nature of the former and the stimulus sensitivity of the latter make their clinical distinction straightforward. Generalized tetanus patients are awake during their spasms, and almost always flex their arms rather than extending them.²⁰ The distinction of seizures from movement disorders and psychiatric conditions is discussed earlier.

EEG monitoring is frequently useful in SE,⁴² but treatment should not be delayed to obtain it when the diagnosis is apparent. A variety of EEG findings may be present, depending on the type of SE and its duration (see Table 65.2). The most typical pattern early in SE is that of rhythmic, high-frequency (>12 Hz) activity that increases in amplitude and decreases in frequency, finally terminating abruptly and leaving postictal low-amplitude slowing in its wake. CPSE patients often lack such organized discharges, but may instead have waxing and waning rhythmic activity in one or several head regions. Such a pattern requires a high index of suspicion in order to correctly diagnose CPSE; a diagnostic trial of an intravenous benzodiazepine is often necessary. Patients who develop refractory SE or experience seizures during neuromuscular blockade will require continuous EEG monitoring. The technology to perform such monitoring outside specialized epilepsy centers is only now becoming available.

MANAGEMENT APPROACH

THE INTENSIVE CARE UNIT PATIENT WITH NEW-ONSET SEIZURES

Deciding whether to administer anticonvulsants to an ICU patient who experiences a single seizure or a few seizures requires a provisional etiologic diagnosis, an estimate of the

likelihood of seizure recurrence, and an understanding of the utility and limitations of available anticonvulsants. For example, the patient who seizes during ethanol withdrawal will probably not benefit from chronic anticonvulsant treatment, and the administration of phenytoin (PHT) will not prevent more withdrawal convulsions during the same episode. Such a patient may need prophylaxis against delirium tremens with benzodiazepines, but the seizures themselves seldom require treatment. The patient who seizes during barbiturate or benzodiazepine withdrawal, in contrast, should usually receive short-term treatment (usually with lorazepam [LRZ]) to prevent the development of SE. Seizures due to drug intoxications or metabolic disturbances should similarly be treated for a brief period, but do not indicate chronic anticonvulsant therapy.

The ICU patient with CNS disease who has even a single seizure should usually be started on a chronic anticonvulsant regimen, with the decision to continue medication reviewed prior to hospital discharge. It is now apparent that initiating anticonvulsant therapy after the first *unprovoked* (e.g., not drug- or withdrawal-related) seizure helps delay the onset of subsequent seizures, but does not change their eventual incidence.⁴³ Starting treatment after the first seizure in a critically ill patient who has a condition predictive of seizure recurrence may be even more important if the patient's problems include coagulopathies, myocardial ischemia, or other conditions that would be seriously complicated by a convulsion.

The Neurocritical Care Society recently published extensive guidelines for the treatment of SE,⁴⁴ which should be consulted for detailed information about the drugs discussed briefly here.

In the ICU setting, PHT (20 mg/kg loading dose, no faster than 50 mg/minute, followed by an initial maintenance dose of 5 mg/kg/day) is often chosen to prevent subsequent seizures because of its relative ease of administration. Slowing the infusion rate to less than 25 mg/minute can usually prevent hypotension and cardiac arrhythmias that may complicate its rapid intravenous administration. Because of the possible precipitation of third-degree atrioventricular (AV) block, an external cardiac pacemaker should be available when patients with conduction abnormalities receive intravenous PHT. Patients who are not actively seizing can be loaded enterally over 6 to 12 hours. Although fosphenytoin is safer than PHT, if it extravasates, this agent does not have less cardiovascular toxicity. Fosphenytoin can also be used for intramuscular loading; PHT (pH 12) should not be administered intramuscularly because it produces myonecrosis.

The total PHT serum concentration should be kept in the "therapeutic" range of 10 to 20 µg/mL while the patient is in the ICU, unless further seizures occur; the level may then be increased until signs of toxicity occur. If the patient is unable to express these signs (e.g., ataxia) because of his or her underlying condition or its treatment, failure to prevent seizures at a concentration of 25 µg/mL is usually an indication to add phenobarbital (PB) (see later). Although the usual goal of chronic anticonvulsant treatment is to administer the smallest dose of a tolerated single agent that completely controls seizures, such an approach is often impossible in the critical care environment. When the patient is more stable, an attempt to

decrease minor side effects or to convert to monotherapy may then be made.

PHT is normally about 90% protein bound. Patients with renal dysfunction will have lower total PHT levels for a given dose because the drug is displaced from its binding sites, but the “free” (unbound) level is not affected. Thus, in renal failure patients, and perhaps in others who are receiving highly protein bound drugs (which will compete for PHT binding sites), it may be advantageous to measure free PHT levels. Because only the free fraction is significantly metabolized, the dose need not be altered with changing renal function. Calculations of the unbound concentration based on the serum albumin concentration are unreliable. The half-life for PHT clearance in patients with normal liver function varies from about 20 hours for the intravenous form and the oral solution to over 24 hours for the extended-release oral capsules. Hence, a new steady-state serum concentration will take 4 to 6 days to establish. The drug need not be given more often than every 12 hours; the dosage interval for the enteral forms depends on the preparation but may be even longer. Hepatic dysfunction will mandate a decrease in the maintenance dose; if the serum albumin is very low, the loading dose can be reduced as well.

Hypersensitivity to PHT is the major adverse effect of concern to the intensivist. This allergy may be manifested solely as fever, but more commonly includes a rash and eosinophilia. Febrile reactions appear to be more common with intravenous than with enteral loading. The Stevens-Johnson syndrome occurs rarely. The diagnosis and management of adverse reactions to PHT and other anticonvulsants have been reviewed.⁴⁵ PHT is associated with a number of long-term adverse effects in patients with subarachnoid or intracerebral hemorrhage.⁴⁶

PB (10-20 mg/kg loading dose, followed by an initial maintenance dose of 1.5 mg/kg/day) remains useful as an anticonvulsant for patients who cannot tolerate PHT, or who have breakthrough seizures after *adequate* PHT loading. The target level for PB in ICU patients should be 20 to 40 µg/mL. Either hepatic or renal dysfunction may affect PB metabolism. The half-life for PB clearance is about 96 hours. Thus, maintenance doses of this agent need be given only once a day, and a steady-state level will take about 3 weeks to be established. Sedation is the major adverse effect; allergy is rare.

Carbamazepine, one of the most useful chronic anticonvulsants, is seldom introduced to critically ill patients because its insolubility has precluded a parenteral formulation. Oral loading with carbamazepine in conscious patients may produce coma lasting several days. It should be recalled as a cause of hyponatremia in patients receiving it chronically.

Valproate should be avoided in settings in which liver disease or hyperammonemia may be problems but is otherwise a useful drug available both orally and intravenously. A loading dose of 30 mg/kg is reasonable.

The place of the newer anticonvulsants in critical care is not well established. Levetiracetam has gained substantial popularity because of its limited drug interactions; it is predominantly excreted by the kidney, so the dose must be adjusted in renal insufficiency. The usual dose for seizure

prevention is between 500 and 1500 mg/day, although doses up to 6 g/day have been employed. The role of serum concentrations for assessment of efficacy or toxicity is not yet established. Lacosamide is also available intravenously and is started at a dose of 200 mg twice daily.

STATUS EPILEPTICUS

The patient in GCSE has an obvious medical emergency; unfortunately, the NCSE and CPSE patients also require emergent treatment but are less straightforward to recognize. In a patient with any of these three conditions, the clinician must move quickly to stop seizures in order to prevent further brain destruction.⁴⁷ A suggested management protocol for these conditions is presented in [Box 65.3](#), and [Figure 65.3](#) shows a management algorithm for SE. Patients with simple partial SE or EPC appear to be at substantially less risk of developing widespread cerebral damage and also appear less likely to respond to the aggressive approach outlined in [Box 65.3](#). In this group, correction of underlying problems, if possible (such as nonketotic hyperosmolar hyperglycemia), is most important. Of the available anticonvulsants, PB seems most likely to be efficacious. These patients are often loaded with PHT in the hope that this agent will prevent secondary generalization, but the actual value of this practice is unknown.

Some frequent errors in the use of medications to terminate SE include (1) use of inadequate doses of potentially effective agents and, conversely, (2) continued administration of drugs that are ineffective in the patient being treated. The first point most frequently applies to PHT; the proverbial “gram of Dilantin” is not adequate for patients weighing more than 50 kg.

SPECIFIC AGENTS

Benzodiazepines

LRZ is emerging as the agent of first choice for terminating SE. A study in the Veterans Affairs medical system compared LRZ, DZ followed by PHT, PHT alone, and PB as first-line agents and demonstrated that LRZ is the definitive agent of first choice.⁴⁸ The advantages of LRZ over PHT include (1) its longer duration of action against SE (4-14 hours as opposed to 20 minutes) and (2) a higher initial response rate.⁴⁹ One study concluded that children receiving PHT for SE were far more likely to require intubation for ventilatory failure than comparable children receiving LRZ⁵⁰; the same was true for all ages in the San Francisco Prehospital Status Study.⁵¹ PHT and LRZ remain the only agents in this class with FDA indications for SE. In Europe, midazolam (MDZ) or clonazepam is often used initially. MDZ is exceptionally useful for refractory SE, but it is hampered by tachyphylaxis,⁵² which occurs because the GABA_A receptors bearing benzodiazepine-sensitive subunits are removed from the neuronal cell membrane and replaced with receptors bearing benzodiazepine-insensitive ones.⁵³ Respiratory depression is the major adverse effect of all agents in this class when administered intravenously.

Data from the Veterans Affairs cooperative trial indicate that the use of other conventional agents after failure of the first one is very unlikely to terminate SE.⁴⁹

Box 65.3 Suggested Therapeutic Sequence for Terminating Status Epilepticus (SE)

- I. Establish airway.
Often the most rapid way to accomplish this is to rapidly terminate SE. If endotracheal intubation under neuromuscular junction blockade is necessary, use a nondepolarizing agent such as rapacuronium (1.5 mg/kg) or vecuronium (0.1 mg/kg). If increased intracranial pressure is a concern, premedicate with lidocaine (1 mg/kg) or thiopental (4-5 mg/kg). If these agents are used, the patient should be considered still to be in SE until neuromuscular transmission is reestablished, or until an EEG demonstrates that SE is no longer present.
- II. Determine blood pressure.
If the patient is hypotensive, begin volume replacement and/or vasoactive agents as clinically indicated. Patients with GCSE who present with hypotension will usually require admission to a critical care unit. (Hypertension should not be treated until SE is controlled, because terminating SE will usually substantially correct it, and many of the agents used to terminate SE can produce hypotension).
- III. Unless the patient is known to be normo- or hyperglycemic, administer dextrose (1 mg/kg) and thiamine (1 mg/kg).
- IV. Terminate SE.
We recommend the following pharmacologic protocol (see text for discussion of these and alternative agents). Be cognizant of the potential of these drugs to eliminate the visible convulsive movements of GCSE while leaving the patient in nonconvulsive SE. Patients who do not begin to respond to external stimuli 15 minutes after the apparent termination of GCSE should be considered at risk for nonconvulsive SE and undergo emergency EEG monitoring.
 - A. Administer LRZ 0.1 mg/kg at 0.04 mg/kg/min.
This drug should be diluted in an equal volume of the solution being used for intravenous infusion, because it is quite viscous. Most adult patients who will respond have done so by a total dose of 8 mg. The latency of effect is debated, but lack of response after 5 minutes should be considered a failure.
 - B. Give MDZ if SE persists.
Administer MDZ 0.2 mg/kg as a bolus, followed by an infusion of 0.1-2.0 mg/kg/hr to achieve seizure control (as determined by EEG monitoring). We routinely intubate patients at this stage if this has not already been accomplished. Patients reaching this stage should be treated in a critical care unit.
 - C. Give propofol if MDZ is not effective.
Should the patient's SE not be controlled with MDZ, administer propofol at a dose of 50-250 µg/kg/min.
- D. Give pentobarbital if propofol is not effective.
If propofol fails, use pentobarbital 12 mg/kg at 0.2-0.4 mg/kg/min as tolerated, followed by an infusion of 0.25-2.0 mg/kg/hr as determined by EEG monitoring (with a goal of burst suppression). Most patients will require systemic and pulmonary arterial catheterization, with fluid and vasoactive therapy as indicated to maintain blood pressure. Other complications of this treatment are discussed in the text.
- V. Prevent recurrence of SE.
The choice of drugs depends greatly on the contributing/causative disorder and the patient's medical and social situation. In general, patients who have not previously received anticonvulsants whose SE is easily controlled often respond well to chronic treatment with PHT or carbamazepine. By contrast, others (e.g., patients with acute encephalitis) will require two or three anticonvulsants at "toxic" levels (e.g., PB in doses greater than 100 µg/mL) to be weaned from MDZ or pentobarbital, and may still have occasional seizures.
- VI. Treat complications.
 - A. Rhabdomyolysis
Rhabdomyolysis should be treated with a vigorous saline diuresis to prevent acute renal failure; urinary alkalization may be a useful adjunct. If definitive treatment of GCSE takes longer than expected because of hypotension or arrhythmias, neuromuscular junction blockade under EEG monitoring might be considered.
 - B. Hyperthermia
Hyperthermia usually remits rapidly after termination of SE. External cooling usually suffices if the core temperature remains elevated. In rare instances, cool peritoneal lavage or extracorporeal blood cooling may be required. High-dose pentobarbital generally produces poikilothermia.
 - C. Cerebral edema
The treatment of cerebral edema secondary to SE has not been well studied. When substantial edema is present, SE and cerebral edema are likely to be manifestations of the same underlying condition. Hyperventilation and mannitol may be valuable if edema is life-threatening. Edema due to SE is vasogenic, so steroids may be useful as well.

EEG, electroencephalogram; GCSE, generalized convulsive status epilepticus; LRZ, lorazepam; MDZ, midazolam; PB, phenobarbital; PHT, phenytoin.

Hydantoins

PHT is an effective anti-SE agent but cannot be delivered rapidly enough to be used as a first-line agent. Its major advantage is a very long duration of action once an adequate dose has been administered (the 20-mg/kg loading dose reliably produces a total serum concentration above 20 µg/mL for 24 hours). Concerns about its intravenous administration were discussed earlier. If the patient is no longer in SE during PHT administration, a slower rate should be employed.

PHT is highly insoluble, and it must be dissolved in sodium hydroxide and propylene glycol at a pH greater

than 11 to remain in solution. Therefore, extravasation can produce severe necrosis. The drug can also cause thrombophlebitis, which may result in the "purple glove syndrome."⁵⁴

Fosphenytoin is a PHT prodrug, which is converted to PHT by phosphatases with a half-life of about 7 minutes. It is prescribed in "PHT equivalents," so the loading dose remains 20 mg/kg. The maximal recommended rate of infusion is 150 mg/minute, but it should be started more slowly and increased to this rate if tolerated. Because it is water-soluble, extravasation does not pose the problem of skin and soft tissue necrosis.

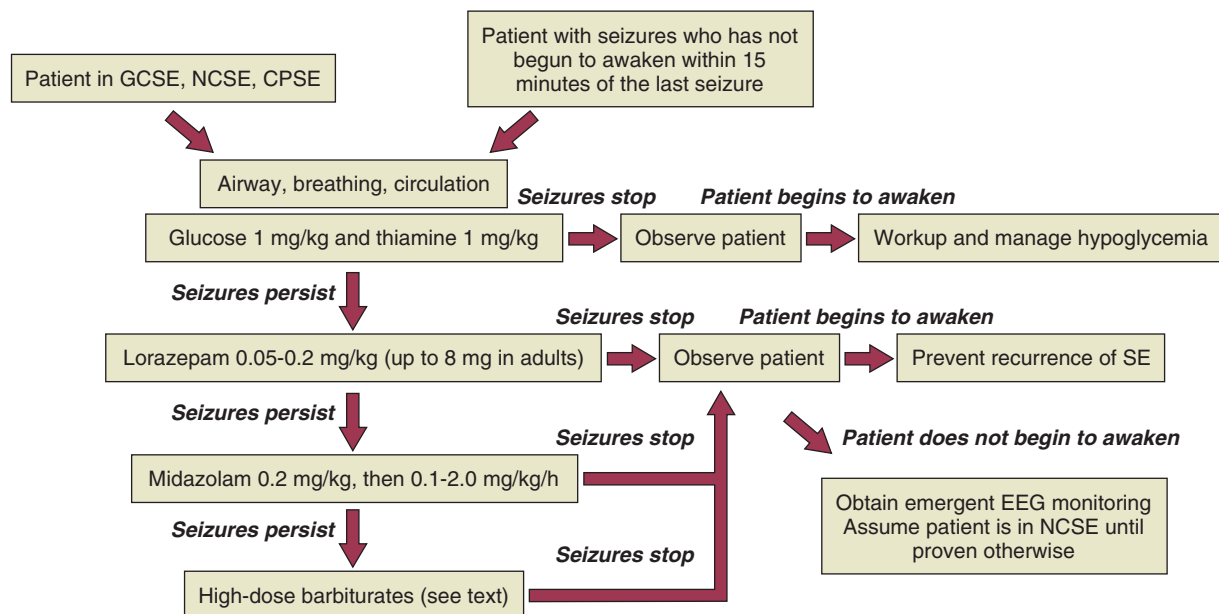

Figure 65.3 Management algorithm for status epilepticus.

Hydantoins should not be used in absence SE, as they may worsen the condition.

Barbiturates

PB has long been one of the major anti-SE agents. Some advocate it as a first-line drug,⁵⁵ but it is rarely used in this role. It has classically been a third-line agent for control of SE, after a benzodiazepine and PHT. Its utility in SE is diminished by the length of time required to obtain a therapeutic effect in patients who have already failed with a benzodiazepine and PHT. It remains an important agent in patients with simple partial SE, and in preparing patients to be withdrawn from high-dose pentobarbital.

Pentobarbital and thiopental are commonly reserved for the control of refractory SE, although thiopental is not currently available in the United States. Although these agents will be effective if used in large enough doses, side effects often limit their use⁵⁶ or may even be fatal.⁵⁷ They are important when other rapidly available modalities have failed (see Box 65.3).

Valproate

Intravenous valproate, given in a dose of 20 to 30 mg/kg, has gained popularity for the treatment of SE because it does not produce respiratory depression or marked sedation. It has been successful in case series^{58,59} but has not been directly compared to the other available agents. Hypotension may occur with large doses.⁶⁰ This drug should be avoided if the patient has an inborn error of metabolism affecting the liver, as it may precipitate fulminant hepatic failure.⁶¹ Valproate has a number of drug interactions that limit its utility in the ICU.⁶²

Isoflurane and Desflurane

The inhalational anesthetics isoflurane and desflurane are effective in controlling refractory SE, but the difficulties involved in delivering the gases (such as the requirement for an anesthesia machine) and the need for a gas

scavenging system have essentially confined their use to the operating suite or the recovery area.⁶³ Advances in delivery systems may make its use in the ICU more reasonable, but long-term use is potentially hepatotoxic.

Propofol

Propofol has been reported effective in refractory SE in doses up to 250 µg/kg/minute⁶⁴ but has not been directly compared with other drugs. It theoretically offers a lower risk of respiratory depression and more rapid recovery of consciousness after the agent is stopped. We use it in SE patients who have failed or become resistant to MDZ.⁶⁵ One should observe for evidence of the propofol infusion syndrome and stop the drug should a metabolic acidosis or evidence of muscle injury develop.

Ketamine

Although only anecdotes and small case series are available, ketamine appears to be a useful agent for the termination of refractory SE.⁶⁶ Its NMDA blocking effect distinguishes it from the other agents discussed here, and it carries theoretical advantages in terms of brain protection.⁶⁷ Its intrinsic sympathomimetic effect makes it a useful choice in hypotensive patients, and it does not markedly impair ventilation. The appropriate dose in SE has not been established; we use a loading dose of 1 to 5 mg/kg, with an infusion rate of 10 to 50 µg/kg/minute.

Levetiracetam

Levetiracetam is now available for intravenous use, but its role in SE remains to be determined. The effective dose in adults is reported to be between 1 and 6 g/day.⁶⁸ Oral administration may be useful for maintenance.⁶⁹

Lacosamide

Lacosamide, which is available for both intravenous and oral use, is typically started at 200 mg twice daily and may be increased to 400 mg twice daily if needed.⁷⁰

The management of “super-refractory” SE has long been an area of contention. These patients may require general anesthesia for a month or longer, while the stimulus for epileptogenicity comes under control or remits. Some of these patients are now recognized to have an autoimmune or paraneoplastic cause for their condition, which requires immunologic therapy.⁷¹ Although these patients sometimes seem hopeless, it is important to remember that 35% will return to their premorbid level of function.⁷²

CONTROVERSIAL MANAGEMENT ISSUES

Controversy remains regarding the long-term neurologic consequences of two clinical conditions: periodic lateralized epileptiform discharges (PLEDs) and EPC. PLEDs are an EEG phenomenon usually seen in the setting of large acute strokes or rapidly expanding mass lesions (e.g., tumors or abscesses). Less commonly, acute metabolic or toxic disorders will “reactivate” PLEDs in the vicinity of an old lesion. The EEG activity signifies the repetitive, synchronous firing of large numbers of neurons near the lesion; there is occasionally contralateral myoclonic jerking of the hand or face. Expert opinion is divided regarding the possibly epileptic nature of these phenomena. Patients who have clinical seizures (i.e., other than the myoclonic jerks) should receive anticonvulsants. The myoclonic movements associated with PLEDs are difficult to suppress without resorting to high-dose barbiturates or benzodiazepines. The data available do not suggest that suppressing the electrical phenomenon improves outcome.

EPC is usually diagnosed in a patient who has an isolated repetitive movement (usually of the hand or face), often following an infectious or vascular insult, or in the setting of nonketotic hyperglycemia.⁷³ The movement may persist for months or years. Most patients receive anticonvulsants to prevent spread of the discharge, but these agents seldom affect EPC itself. Attempts at treatment with high-dose barbiturates result in short-term suppression of the movement, but it usually returns as the drug levels decline.

Another area of contention concerns the periodic epileptiform discharges occasionally seen after respiratory or cardiac arrests. Because experimental studies show that neurons in anoxic animals exhibit epileptiform behavior, some have raised the possibility that these discharges are a form of SE and should therefore be treated. Although this possibility has not been systematically studied in humans, the lack even of anecdotes of neurologic improvement with anticonvulsant treatment suggests that currently available anticonvulsant drugs do not improve patient outcome in this condition. If it is associated with myoclonus that the family finds disconcerting, suppression of the movements with neuromuscular junction blockers may be useful. High-dose barbiturates or benzodiazepines will also stop the movements, but they obscure the neurologic examination and complicate the possible diagnosis of brain death. These drugs do not improve prognosis in postanoxic patients.

PROGNOSIS

Wijdicks and Sharbrough reported that 34% of patients experiencing a seizure in any ICU at the Mayo Clinic died

during that hospitalization.¹¹ In our prospective study of neurologic complications in medical ICU patients,¹⁰ having even one seizure while in the unit for a non-neurologic reason doubled the patient’s in-hospital mortality rate. This effect on prognosis appeared to be due to the effect of the cause of the ictus, rather than the seizure itself.

Three major factors determine the outcome of SE: the type of SE, its cause, and its duration. In general, GCSE carries the worst prognosis for neurologic recovery as a consequence of SE itself; myoclonic SE following an anoxic episode carries a very poor prognosis for survival. CPSE produces some risk of limbic system damage, usually manifested by memory dysfunction. Simple partial SE may produce neuronal damage, but this is difficult to discern from the effect of the lesion that commonly produces this form of SE. At the far end of the spectrum, absence SE does not seem to carry a risk of neurologic deterioration.

Most studies of SE outcome have concentrated on mortality rates in GCSE. Hauser¹⁸ summarized the data available in 1990, showing mortality rates for SE to vary from 1% to 53%. The few studies that attempted to distinguish the mortality rate due to SE from that of the underlying disease attributed rates of 1% to 7% to SE and 2% to 25% to its cause. The Virginia Commonwealth University population-based studies have analyzed the mortality risks for various aspects of GCSE.¹² SE lasting longer than 1 hour was associated with a 10-fold increase in mortality rate when compared to SE lasting less than 1 hour. Other causes associated with marked increases in mortality rate were anoxia, intracranial hemorrhages, tumors, infections, and trauma.

Very few findings are available regarding the functional status of GCSE survivors, and none reliably allows a distinction between the effects of SE and its causes. A review of intellectual impairment as an outcome of SE concluded intellectual abilities probably did decline as a consequence of SE.⁷⁴ Survivors of SE frequently have memory and behavioral disorders out of proportion to any structural damage produced by the cause of their seizures. This observation is supported by a wealth of experimental data and argues strongly for the rapid and effective control of SE. The prognosis of CPSE is less certain, but case reports of severe memory deficits following prolonged CPSE have appeared.⁷⁵

The effect of the treatment of SE on the risk of subsequent epilepsy is uncertain. Experimental studies suggest that SE does lower the threshold for subsequent seizures.⁷⁶

KEY POINTS

- Seizures lasting longer than 1 hour markedly increase mortality risk compared to seizures lasting less than 1 hour.
- Primary generalized seizures arise from the entire cerebral cortex without evidence of focal point.
- In addition to damaging the CNS, GCSE produces serious, often life-threatening, systemic effects that include cardiovascular, respiratory, and muscular systems.

Continued on following page

KEY POINTS (Continued)

- Hypersensitivity to PHT is the major adverse effect of concern to the intensivist. This allergy may be manifested solely as fever but more commonly includes a rash and eosinophilia. Rarely Stevens-Johnson syndrome occurs.
- The patient who seizes during ethanol withdrawal will probably not benefit from chronic anticonvulsant treatment, and the administration of PHT will not prevent more withdrawal convulsions during the same episode.
- Errors in the use of medications to terminate SE include (1) use of inadequate doses of potentially effective agents and, conversely, (2) continued administration of drugs that are ineffective in the patient being treated.
- Myoclonic SE following an anoxic episode carries a very poor prognosis for survival.

CONCLUSIONS

INTRODUCTION

In the context of critical care medicine, the management of severe head injuries remains the Achilles' heel of neurosurgery, as borne out by our own observations over three decades of practice at academic centers. Although revolutionary advances now allow imaging of the brain and spinal cord with greatly improved speed and anatomic detail, translation of this resource into better outcomes has been disappointing. The search for a neuroprotective agent that can consistently prevent the deadly cascade of events that leads to irreparable brain damage remains for future investigators as of this writing.

Key to optimizing clinical outcomes has been the recognition that the time from injury to surgery must be as short as possible to minimize the secondary manifestations of serious brain trauma. Other valuable lessons from clinical experience reported in the literature are that glucocorticoids have no significant therapeutic benefit in managing severe head injuries and that hyperventilation, very effective in reducing high intracranial pressure (ICP), must be used judiciously; otherwise, it may become more harmful than helpful.

It also has been demonstrated that the management of serious brain trauma requires specialty teams consisting of experienced neurosurgeons, traumatologists, and intensivists (specifically, neurointensivists) working together in a dedicated unit equipped and staffed to optimally care for

these patients. In the absence of such facilities, outcomes suffer.¹⁻³

Finally, the introduction of a simple-to-use and highly predictable neurologic status scoring system, the Glasgow Coma Scale (GCS), has enabled meaningful multidisciplinary communication from the accident scene through intensive care and beyond, resulting in efficient and timely triage and treatment of these patients in tenuous conditions.

INCIDENCE

The Centers for Disease Control and Prevention report the number of patients sustaining a traumatic brain injury (TBI) to be at least 1.7 million per year in the United States. Approximately 80% of patients are released from the emergency department, 275,000 are admitted, and 52,000 die. Nearly a third of all traumatic deaths in the U.S. involve a head injury. The ages most likely to sustain a TBI are children up to 4 years old and adults over 64, with adults greater than 74 years old having the highest rates of hospitalization and death associated with head injury.⁴ Teenagers and young adults continue to be at high risk for sustaining TBI, but the range has decreased over the past 20 years from between 15 and 24 to between 15 and 19.^{4,5} The incidence of head injury has been shown to be inversely proportional to economic status,⁶ and has remained up to three times more common in males in every age group over the past

several decades.^{4,7,8} In the United States, falls are the most common cause of TBI and are responsible for half of the head-injured children up to 14 years of age and 60% of the adults over the age of 64.⁴ Although the frequency of head injury related to motor vehicle crashes has decreased over the years to a little less than 20%, these crashes are the second leading cause of head injury in all age groups and result in the largest percentage of TBI-related deaths.^{4,9} The incidence of TBI worldwide is difficult to quantify but is estimated to be at least 10 million people a year, with traffic accidents accounting for more than half, and falls being the second leading cause;¹⁰ this is the opposite distribution seen in the United States.⁴ Violence is estimated to cause about 10% of head injuries throughout the world,¹⁰ as well as in the U.S.,⁴ but there is significant variability in the specific mechanisms. For example, between 1997 and 2007 in the U.S., firearms were related to just over a third of all lethal TBIs, compared to a single hospital in South Africa that reported its experience with more than 300 stab wounds to the brain.¹¹

DIAGNOSTIC APPROACH

The presenting neurologic condition of patients with head injuries is the primary factor in determining the initial management and prognosis. When a detailed history is unavailable, it is important to keep in mind that loss of consciousness may have preceded and in fact caused the traumatic event, such as aneurysmal subarachnoid hemorrhage (SAH), hypoglycemia, intoxication, or syncope. Level of consciousness is one of the most important neurologic considerations in managing a head-injured patient. Neurosurgical patients generally have an alteration in level of consciousness from either brainstem or bilateral cerebral hemispheric involvement. This may be secondary to poor perfusion due to high ICP or brainstem compression, both of which require neurosurgical intervention. Therefore, an accurate tool to measure level of consciousness is essential. Many clinical assessment tools are available for use in the critical care setting.¹²⁻²⁴

GLASGOW COMA SCALE

Ideally, using the GCS, a nurse, medical student, paramedic, physician assistant, intensivist, trauma surgeon, emergency medicine physician, neurologist, and neurosurgeon all should obtain the same score when assessing a patient. The GCS system is not perfect, but it has proved itself to be, overall, a practical, straightforward grading system that can be used by health professionals in various fields and at different levels to produce reliable results.²⁵⁻³⁰ The GCS has become the most widely used assessment tool and is considered the gold standard for the evaluation of patients with head injuries.¹²

The GCS is a measure of level of consciousness and does not take into account focal deficits. It is based on eye opening (1-4), verbal response (1-5), and motor response (1-6) (Table 66.1). A patient with a normal level of consciousness should have the highest possible score of 15. The lowest score possible is 3, not 0 as might be expected. An intubated patient technically gets a 1 for verbal response and is assigned 1T (for Tube) for the verbal score. It is

Table 66.1 Glasgow Coma Scale

Component	Score
Eye Opening	
Spontaneously	4
To voice	3
To pain	2
No response	1
Verbal	
Oriented	5
Disoriented	4
Inappropriate	3
Incomprehensible sounds	2
No response	1
Motor	
Following commands	6
Localizing to pain	5
Withdrawing to pain	4
Abnormal flexion	3
Abnormal extension	2
No response	1

important to identify the score for each observed variable tested. For example, a typical score for an intubated patient with decorticate posturing probably would be E1 + V1T + M3 = 5T (where E denotes eye opening, V is verbal response, and M is motor response). It also is important to realize the shortcoming of this system in evaluating patients with dementia or aphasia. A point to keep in mind is that the GCS attempts to put a numeric value on level of consciousness, with 15 being representative of normal. If a demented patient from a nursing home presents with a normal level of consciousness after a fall but doesn't know what day it is, the GCS would be calculated as E4 + V4 + M6 = 14. A GCS score of 14 describes a patient with an abnormal level of consciousness but fails to accurately communicate this particular patient's condition. Likewise, clinicians must use caution when applying the GCS to patients with aphasia. Conversely, patients with profound focal deficits and a normal level of consciousness should have a GCS score of 15. Another problematic case is that of a quadriplegic patient with a normal level of consciousness who is able to blink the eyes or stick out the tongue upon command, thereby giving a top score of 6 on the motor assessment.

The GCS has been used to predict outcome.³¹ The motor score itself has predictive value as well.³² The GCS score should be calculated after hemodynamic and pulmonary resuscitation and without sedatives or muscle relaxants.³³

Aggressive implementation of early sedation and intubation in severely head-injured patients compromises the ability to determine an accurate GCS score.³⁴

COMPUTED TOMOGRAPHY CLASSIFICATION: MARSHALL CLASSIFICATION

A useful classification of brain injuries by findings on computed tomography (CT) has been devised by Marshall and colleagues. This CT classification, presented in Table 66.2, can serve as a guide in describing scans and has strong predictive power.^{34,35}

Table 66.2 Marshall Computed Tomography Classification

Category	Definition
Diffuse injury I (no visible pathology)	No visible intracranial pathology seen on computed tomography scan
Diffuse injury II	Cisterns are present with midline shift of 0-5 mm or lesion densities present no high- or mixed-density lesion > 25 cm ³ may include bone fragments and foreign bodies
Diffuse injury III (swelling)	Cisterns compressed or absent with midline shift of 0-5 mm; no high- or mixed-density lesion > 25 cm ³
Diffuse injury IV (shift)	Midline shift > 5 mm; no high or mixed-density lesion > 25 cm ³
Evacuated mass lesion	Any lesion surgically evacuated
Nonevacuated mass lesion	High- or mixed-density lesion > 25 cm ³ ; not surgically evacuated

From Marshall LF, Marshall SB, Klauber MR, et al: A new classification of head injury based on computerized tomography. *J Neurosurg* 1991;75:S14-S20.

Maas and associates have proposed a scoring system with better predictive power (Table 66.3), with a sum total adjusted to be consistent with the GCS.³⁴ Table 66.4 presents a mortality prediction chart based on this classification.

This scoring system is best used as one piece of data in the overall clinical assessment in considering a patient's prognosis.³⁶

PREDICTION OF OUTCOMES

Severe brain injury outcomes can be accurately predicted using four variables: age, GCS score on admission (especially motor score), CT characteristics, and presence of ischemic and hemodynamic secondary insults. Using these four predictors, numerous investigators have used statistical modeling techniques to predict up to 80% or more of outcomes.³⁷

Head injuries generally are classified as mild (GCS score of 13 to 15), moderate (GCS score of 9 to 12), or severe,^{3,8} although the evidence may be sufficient to include a GCS score of 13 in the moderate category.³⁸

CT scanning is the diagnostic imaging study of choice in trauma. Plain x-ray films of the skull are rarely indicated as a screening study for head-injured patients. Outcomes with the strategy of obtaining CT scans in all head-injured patients are superior to those with other management strategies. The incidence of missed surgical lesions in mildly head-injured patients by CT scanning is 0.028%.³⁹⁻⁴²

PRIMARY HEAD INJURY

Primary head injury can be defined as the damage that occurs at the moment of impact and can take the form of skull

Table 66.3 Prognostic Score Chart for Probability of Mortality in Patients with Severe or Moderate Traumatic Brain Injury by Computed Tomography Characteristics

Predictor	Score
Basal Cisterns	
Normal	0
Compressed	1
Absent	2
Midline Shift	
No shift or shift < 5 mm	0
Shift > 5 mm	1
Epidural Mass Lesion	
Present	0
Absent	1
Intraventricular Blood or tSAH	
Absent	0
Present	1
Sum Score*	+1

*The sum score can be used to obtain the predicted probability of mortality (see Table 66.4). The authors chose to add plus 1 to make the grading numerically consistent with the grading of the motor score of the GCS and with the Marshall CT classification. tSAH, traumatic subarachnoid hemorrhage.

Score	Mortality Rate (%)
1	0
2	6.8
3	16.0
4	26.0
5	53.0
6	61.0

fractures, surface contusions and lacerations, diffuse axonal injury, or diffuse vascular injury.⁴² Some authors include the contusions and hematomas that form as a direct and immediate effect of the impact as part of the primary injury as well.⁴³ These hemorrhages may manifest with significant mass effect requiring surgical intervention.

Emergent neurosurgical intervention is designed to prevent permanent damage to the central nervous system (CNS) in general and to the reticular activating system in particular. Located in the brainstem, the reticular activating system is what allows a meaningful, awake condition; if it is destroyed, the patient will be vegetative. The surgical management of head-injured patients typically is driven by the presence of pathologic masses (hematomas) in anatomic spaces. These spaces are best described by reviewing the anatomic layers.

In virtually all cases of head injury seen in clinical practice, the pathogenic mechanism is an impact. The first

layer involved is the scalp, the layers of which are best remembered by the mnemonic SCALP: S for skin, C for connective tissue, A for galea aponeurosis, L for the loose connective tissue layer, and P for periosteum. The scalp is the thickest skin in the body and absorbs some of the energy delivered to the head during impact. The scalp has a rich blood supply with relatively large blood vessels situated in the space where the connective tissue meets the galea. A large laceration has the potential for heavy blood loss and needs to be managed with local, direct pressure until surgical repair can be accomplished. Care must be taken in applying pressure if there is an underlying depressed skull fracture or, especially, a skull defect as is seen in missile injuries. It should be noted that an unattended, serious scalp laceration does have the potential for blood loss to the point of hemodynamic instability, but this is the only exception to the rule that an adult cannot lose enough blood from any intracranial hemorrhage to cause hypovolemic shock and hemodynamic instability. Blood clots within the scalp usually are limited to the loose connective tissue layer and are referred to as subgaleal hematomas, which may be a feature of massive injuries or a sign of coagulopathy but rarely require treatment other than direct pressure if active bleeding is suspected. A cephalohematoma is a blood clot that expands in the potential space between the periosteum and the skull; this lesion is limited to neonates.

SKULL FRACTURES

The next layer involved in trauma is the skull, composed of outer and inner tables with the intervening vascular diploic space. Skull fractures are best considered as involving the cranial vault or the skull base. Cranial vault fractures are further divided into linear or depressed and open or closed. In general, closed, linear fractures of the cranial vault do not require any specific treatment.

Basilar skull fractures typically are linear and involve the anterior cranial base and the petrous part of the temporal bone. These fractures have the potential for an associated dural laceration adjacent to potentially contaminated paranasal sinuses, or the external ear canal if the tympanic membrane is disrupted. This allows the potential for a cerebrospinal fluid (CSF) fistula to develop, as well as meningitis. Clinical signs of a fracture of the petrous portion of the temporal bone include hemotympanum with or without tympanic membrane disruption, hearing loss, CSF otorrhea, and Battle sign. The cranial nerves that course through the temporal bone include the facial, acoustic, and vestibular nerves; therefore, associated vestibular dysfunction or facial weakness may be noted (Fig. 66.1). Anterior cranial base fractures may be associated with “racoon eyes,” anosmia, and CSF rhinorrhea. It is important to remember that when a fracture of the floor of the anterior cranial base is suspected, a nasogastric tube should not be inserted, because of the risk of intracranial penetration (Fig. 66.2).

The use of prophylactic antibiotics in basilar skull fractures has been debated but generally is not recommended. When CSF leak does occur, the break in the tissue usually will heal with conservative treatment over the course of a week, unless the defect is very large or a bony spicule is identified. Keeping the patient’s head elevated and possibly using external CSF diversion after a few days are reasonable

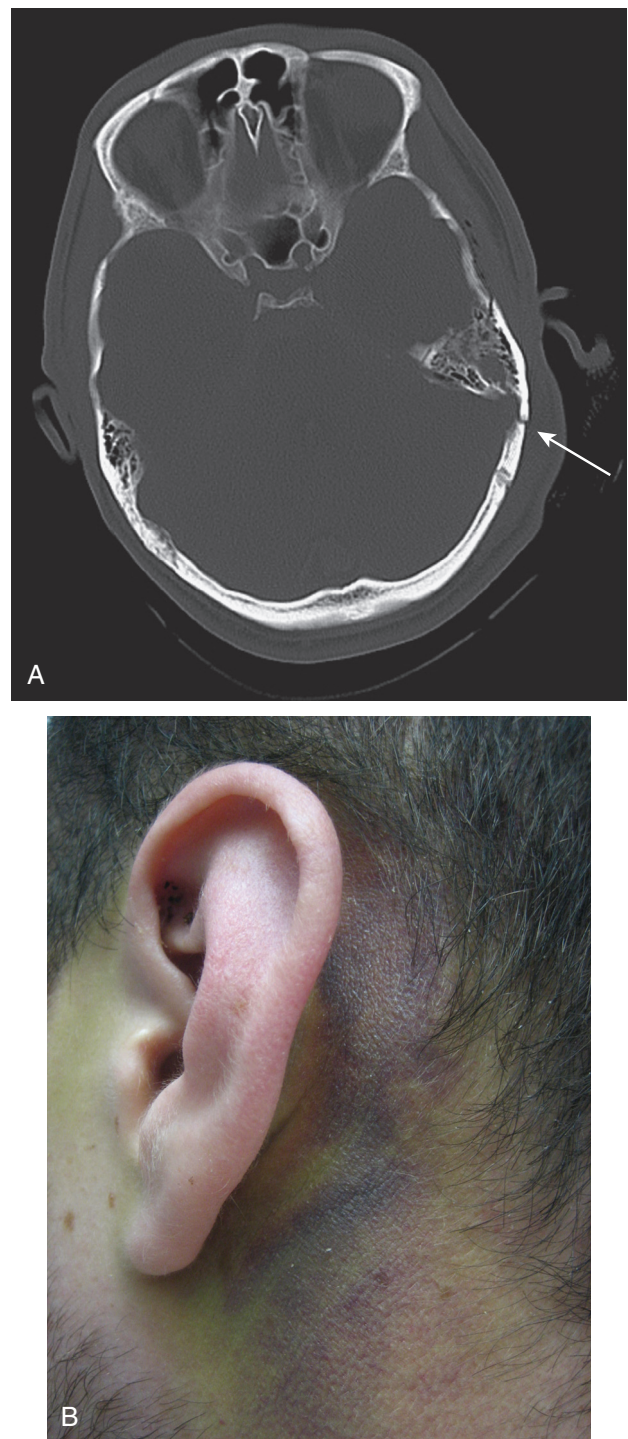

Figure 66.1 A, Axial computed tomography image demonstrating skull base fracture (arrow) through the petrous portion of the temporal bone. B, Battle sign.

nonoperative methods; however, if the leak persists, surgical repair is indicated.⁴⁴

Most depressed skull fractures occur in men younger than 30 years of age.⁴⁵ Despite very little literature to support any particular management strategy, closed depressed skull fractures generally are operated on if the extent of depression is greater than the full thickness of the adjacent skull, with the theoretical benefits of improved cosmetic result, a

Figure 66.2 **A**, Preoperative axial computed tomography image demonstrates multiple anterior cranial base fractures involving the cribriform plate and posterior wall of the frontal sinus (arrows) in a 50-year-old man who fell off a ladder onto his face. The patient sustained minimal brain injury from the impact because the facial and anterior frontal sinuses absorbed much of the energy, cushioning the brain during impact, much like an air bag. **B**, Image from a preoperative sagittal T1 MRI study without contrast demonstrates the tract of a nasogastric tube through the frontal lobe in a 42-year-old woman with an anterior cranial base defect (arrow).

decrease in late-onset posttraumatic epilepsy, and a reduction in the incidence of persistent neurologic deficit.⁴⁶ Most depressed skull fractures, however, are open⁴⁵ (Fig. 66.3), meaning that a scalp laceration with galeal disruption overlying the fracture is present.

Open depressed skull fractures may be associated with significant morbidity and mortality.^{45,47} Infection rates are

Figure 66.3 Depressed skull fracture. **A**, Brain window (arrow). **B**, Computed tomography three-dimensional reconstruction also demonstrates the depressed skull fracture (arrow).

reported to be between 1.9% and 10.6%,⁴⁶⁻⁵⁰ with neurologic morbidity and mortality rates of approximately 11% each⁴⁶ and an incidence of late epilepsy up to 15%.⁵¹

By convention, open depressed cranial vault fractures are treated surgically, with debridement and elevation, primarily to attempt to decrease the incidence of infection. Open depressed cranial fractures may be treated nonoperatively if clinical and radiographic examination reveals no evidence of dural penetration, significant intracranial hematoma, depression greater than 1 cm, frontal sinus involvement, gross cosmetic deformity, wound infection, pneumocephalus, or gross wound contamination.⁴⁶

A special type of depressed fracture is fracture of the frontal sinus. Depression of the fracture may require surgery

A

B

Figure 66.4 Depressed skull fracture requiring urgent decompressive surgery. The patient was a 32-year-old man hit on the back of the head by a metal beam at a construction site who presented with a deteriorating level of consciousness. **A**, Axial computed tomography scan demonstrates an open depressed skull fracture (arrow) at the level of the superior sagittal sinus (SSS) that extended down to the confluence of the transverse and SSS. **B**, Sagittal magnetic resonance venogram demonstrates occlusion of venous outflow (arrow) at the level of the fracture, which necessitated emergency surgical decompression and repair of the SSS.

to prevent CNS infection and CSF leak (Fig. 66.4). Another special type of depressed fracture involves a major dural venous sinus (see Fig. 66.4). Under these circumstances, the risks associated with surgery are increased, and elevation of the fracture fragment generally is reserved for significant compromise of venous drainage.⁴⁴

EPIDURAL HEMATOMA

The next anatomic layer after the skull is the dura, which is the periosteum of the inner table of the skull and, as such, is tightly adherent to the bone. The potential space between the inner table of the skull and the dura is the *epidural space*. Epidural hematomas (EDHs) form in this potential space between the skull and the dura. The most common mechanism for the development of an EDH is a motor vehicle crash (in 53% of the cases), followed by falls (in 30%) and assault (in 8%).⁵²⁻⁶⁰ Typically, bleeding results from damage to the middle meningeal artery, but an EDH also can occur from injury to the middle meningeal vein, diploic veins, or the venous sinuses.⁶⁰

EDHs generally occur in the temporal and temporoparietal regions (Fig. 66.5).^{52,57,61-64} A useful way to describe the development of an EDH is to follow the events that take place when a patient presents with an initial lucid interval following brief loss of consciousness after head trauma. A lucid interval occurs when a patient initially is rendered unconscious from a concussive head injury that causes a linear skull fracture involving the middle meningeal artery or one of its branches. The middle meningeal artery is a dural vessel that runs half in the dura and half through the groove in the inner table of the skull. When a fracture extends across the bony groove of the artery, it will tear and bleed. Because the dura is tightly adherent to the inner table of the skull, significant force is needed to push the dura off the inner table. An arterial hemorrhage generally has enough pressure to strip the dura off the bone, converting the potential epidural space into a mass. The bony attachment of the dura becomes progressively stronger with age; therefore, the dura of a younger patient requires less force to push it off the bone than would be required in an older patient. Not surprisingly, the mean age of patients with EDH is between 20 and 30 years of age,^{53-55,63-70} and EDHs are unusual in patients older than 50.⁶⁰

The growing epidural mass commonly compresses the anterior temporal lobe, which usually will not cause a major detectable neurologic deficit early in the course in the emergency department. During this so-called lucid component of the lucid interval, the patient regains consciousness from the concussive injury while the EDH is expanding and compressing the relatively silent anterior temporal lobe. The medial part of the temporal lobe, the uncus, lies just lateral to the brainstem at the level of the third cranial nerve (oculomotor nerve), which runs alongside the tentorial edge. When the EDH enlarges to the point at which it pushes the uncus of the temporal lobe over the tentorial edge, rapid development of a third nerve palsy, along with brainstem compression, is possible—which, at this level, will cause a contralateral hemiparesis from direct compression of the cerebral peduncle and a decrease in level of consciousness from the effect on the reticular activating system. The classic signs at this point are coma with a dilated pupil ipsilateral to the EDH and a contralateral hemiparesis. Occasionally, instead of directly compressing the ipsilateral cerebral peduncle, the herniating uncus can shift the brainstem into the contralateral tentorial edge, a relatively sharp rigid structure. This can damage the brainstem on the side opposite the EDH and cause a hemiparesis ipsilateral to the

Figure 66.5 The patient was a 58-year-old female pedestrian who was hit by a car and unconscious at the accident scene. She was combative on presentation, pharmacologically paralyzed, and intubated in the trauma bay. **A**, Computed tomography (CT) image shows a small left temporal epidural hematoma without significant mass effect (*large arrow*). Note the right frontal traumatic subarachnoid hemorrhage (*small, thin arrow*) and the small amount of air (*arrowhead*) from the associated open, linear fracture (*arrow*), seen in **B**. There is no significant mass effect, and an intracranial pressure monitor (*arrow*) was placed, seen in **C**. Intracranial pressure (ICP) steadily increased shortly after placement, and immediate follow-up CT scans, shown in **D**, reveal marked expansion of the epidural hematoma with mass effect and shift requiring emergency craniotomy.

Continued on following page

Figure 66.5, cont'd E, Postoperative CT scans reveal adequate decompression of surgical clot, with subsequent development of edema on the right side of the brain.

side of the hematoma. This is known as Kernohan's notch phenomenon.

Taking a general view, the patient goes from unconscious at the time of impact from a concussive injury, to awake, to unconscious again secondary to brainstem compression—hence the term *lucid interval*. The lucid interval is observed in close to half of the patients undergoing surgery for EDH.*

Pupillary abnormalities occur in approximately 20% to 30% of patients with surgical EDH.^{52,54,59,60,67} Cranial fractures are present in between 70% and 95% of the cases.^{54,60,68,70,74,75} Associated intracranial lesions are found in 30% to 50% of adults with surgical EDHs,[†] and subdural or parenchymal lesions in association with EDH lower the chance of a good outcome.⁶⁰

The overall mortality rate (for all ages and GCS scores) is approximately 10%.[‡] The time lapse between the onset of pupillary abnormalities and surgery determines outcome,^{61,66,80} but the single most important predictor of outcome in patients operated on for EDH is the GCS score on admission and before surgery.^{52,53,55,61,81-83}

Not all EDHs, however, require surgery. No prospective randomized trials have been conducted to compare surgical treatment with nonoperative management, nor should there be. Available data describe nonsurgical management in selected cases. In one study, approximately 10% of the total number of EDHs were treated nonoperatively. All were conscious with a GCS score greater than 11 and a midline shift on CT scan of less than 10 mm. Not one of these nonoperative hematomas was in the temporal region.⁸⁴

Another study reported findings in a group of 57 selected patients treated nonoperatively with an initial GCS score of 10 or higher, with maximum hematoma thickness less than 13 mm, with five clots located in the temporal region, but only one patient had a midline shift on CT.⁵³

An interesting approach for dealing with thin, acute EDHs in an early stage has been reported in a small, isolated series of patients using endovascular techniques to occlude

the middle meningeal artery.⁸⁵ Surgical decision making for an acute EDH is based on GCS score, pupillary findings, comorbid conditions, CT findings, age, and, in delayed decisions, ICP. Guidelines for the surgical management of acute EDH published in 2006 recommend surgical evacuation of an EDH less than 30 mL in volume. Smaller hematomas in patients with a GCS score greater than 8 and without focal deficits, clot thickness less than 15 mm, and less than 5 mm of midline shift may be considered for nonoperative management. Close neurologic monitoring and serial CT scanning are essential. Of importance, a temporal location for an EDH is associated with failure of nonoperative management and should lower the threshold for surgery.⁶⁰

Because time between neurologic deterioration and surgery is critical, the question of whether a patient with an acute EDH should receive treatment at the nearest hospital or should be transferred to a trauma center is important. The issue is whether or not a non-neurosurgeon should operate on a patient deteriorating from an acute EDH as a true emergency. One suboptimally controlled study reported worse outcomes in a small group of patients who underwent emergency operations by non-neurosurgeons and attributed this mainly to the technical inadequacy of the operation.^{59,60} Other studies have documented worse outcomes in patients transferred from outlying hospitals for surgery.^{52,73} The take-home message is that EDHs are extra-axial hemorrhages located adjacent to the brainstem that can represent a true neurosurgical emergency, and that rapid, competent decompression makes a difference.

SUBDURAL HEMATOMA

Proceeding deep to the skull, the next space is the subdural space. Unlike the potential epidural space, the subdural space is a real space. It is a compartment that follows the contour of the brain, which is how it appears on a CT scan (Fig. 66.6). Anatomically, bridging veins course through the subdural space from the cerebral hemispheres to the superior sagittal sinus. As the brain accelerates within the skull after impact, these veins can stretch and tear.⁸⁶

The source of bleeding also can be from a cortical artery^{87,88} or vein. These hematomas typically form over the

*See references 52, 55, 60, 65, 69, 71-73.

†See references 52, 54, 55, 57-60, 63-67, 73, 76, 77.

surface or between the cerebral hemispheres, along the tentorium, or between the temporal lobe and base of the skull.

An acute subdural hematoma (SDH), as defined by Bullock and colleagues, appears within 14 days of injury,⁶⁰ although some authors consider an SDH to be subacute when signs and symptoms develop between 3 and 20 days after trauma.⁸⁹

Acute SDHs consist of clotted blood, which is fibrous and often adherent to adjacent tissue. The blood remains clotted for several days. After this time, the clot gradually and progressively lyses, resulting in a mixture of clot and fluid. After several weeks, the clot is liquefied and becomes a chronic SDH. Chronic SDHs may manifest weeks or months after what may have been mild or insignificant trauma. Chronic SDHs occur more often in elderly patients and individuals who have more intracranial space because of cortical atrophy. A membrane often surrounds these hematomas, and the collection of fluid may slowly grow in size because of repeated small bleeds or accumulation of fluid transudate from the membrane.⁸⁶

The incidence of acute SDHs is approximately 20% in severe traumatic brain injury,^{60,90-93} and the mean age is between 31 and 47 years, with most of the patients being men.^{60,94-97} The mechanism of injury differs between age groups, with patients older than 65 more commonly presenting after a fall, and younger patients being involved more often in a motor vehicle crash,^{60,98-100} which, among comatose patients with acute SDH, is the most common mechanism of injury.^{60,91,93,101}

Between 37% and 80% of patients with acute SDH present with a GCS score of 8 or lower,^{60,65,71,94,97,102} and the overall mortality rate is between 40% and 60%.^{*} Mortality rates among comatose patients requiring surgery are somewhat higher, with reported rates between 57% and 68%.[†] Acute

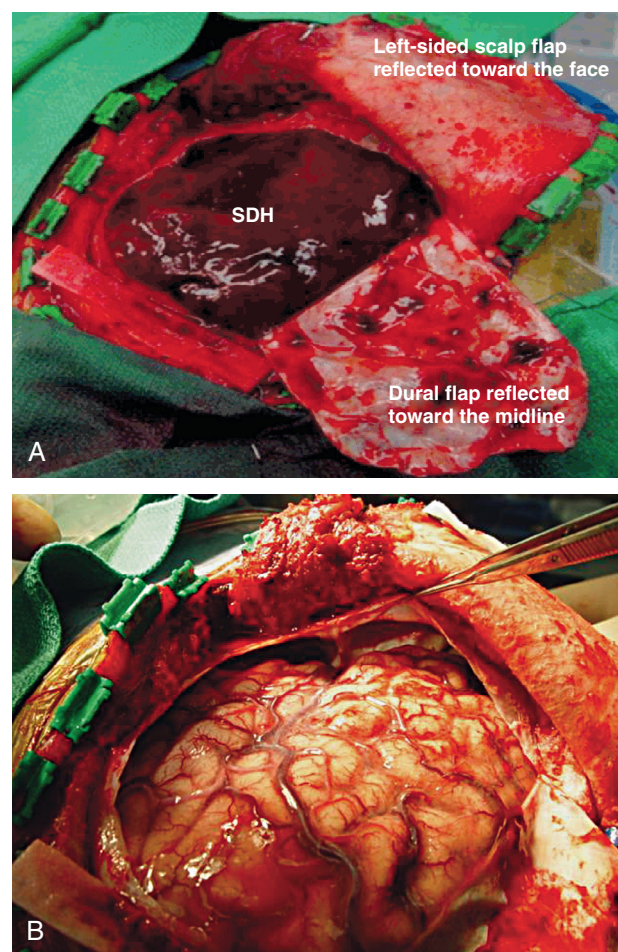

Figure 66.7 **A**, Intraoperative view of a solid subdural hematoma (SDH) on the surface of the brain. **B**, Decompressed brain with demonstration of evacuated subdural space.

subdural hematomas frequently are associated with other brain injuries,^{97,102} which is one of the reasons why the mortality rate is relatively high.

A simple acute SDH is a subdural, extra-axial hematoma without any other associated brain injury (Fig. 66.7). A complex SDH is associated with parenchymal injury (Fig. 66.8).^{107,108} Fewer than half of acute SDHs requiring surgery are isolated, simple lesions.^{60,97,102}

One useful method to identify the presence of associated injury is to measure the thickness of the subdural clot relative to the amount of brain shift on the CT scan. If the amount of shift is directly proportional to the thickness of the extra-axial clot, the injury is likely to be simple and only the brain compressed. However, if the amount of shift is more than expected as indicated by the size of the hematoma, then additional parenchymal brain injury probably is present under the clot, causing additive mass effect. Not surprisingly, the mortality for complex injuries is higher than that for simple SDHs.^{107,108}

In addition to the obvious compressive effects that an SDH generates, the available evidence points to a direct toxic effect of the blood itself on the underlying cortex, thereby compounding the problem.^{109,110}

Age is an important factor in acute SDHs. There is a significant increase in poor outcome among patients older than 60 years of age with severe head injury in

^{*}See references 60, 66, 92, 95, 96, 103-106.

Figure 66.8 **A**, Computed tomography scan of acute, complex left-sided subdural hematoma (SDH) (lower arrow) with mass effect (upper arrow) out of proportion to the size of the clot, indicating more than just the effect of an extra-axial compressive mass—that is, intrinsic, parenchymal brain injury with edema. **B**, Intraoperative photograph of decompressed brain reveals hemorrhagic, inflamed, and edematous brain swelling out through the cranial defect. Compare with the intraoperative photograph of the simple SDH in Figure 66.7.

general.^{93,98-101,111,112} Older patients with an acute SDH and a low GCS score do especially poorly.^{98-101,111,112}

The decision for immediate surgery is dependent on GCS score, age, pupillary examination, comorbidities, CT findings, and salvageability with respect to the patient's level of injury. In addition to all of these factors, decision making for delayed surgery is dependent on clinical course and ICP.⁶⁰

On the basis of a contemporary search of the literature, Bullock and colleagues found that CT parameters of a midline shift greater than 5 mm and a clot thickness greater

than 10 mm were independent factors requiring surgery in salvageable patients. They also identified a select group of comatose patients with smaller SDHs who could be managed nonoperatively if the patients remained neurologically stable with normal pupils and ICP of 20 mm or less.⁶⁰

TRAUMATIC SUBARACHNOID HEMORRHAGE

The subarachnoid space is a CSF-filled compartment within which are the major cerebral blood vessels. The CSF within the subarachnoid space fills the basal cisterns and interdigitates into the cortical sulci. Traumatic SAH can be caused by bleeding of cortical arteries, veins, or brain surface cerebral contusions.¹¹³

In contrast with hemorrhages in other locations, SAH is not a discrete surgical clot that requires evacuation. Trauma is the most common cause of SAH; a ruptured aneurysm is the most common cause of a spontaneous SAH. Aneurysmal SAH generally involves the suprasellar cistern, where the circle of Willis lies. Traumatic SAH can be found as small-volume hemorrhages in the sylvian fissures and especially in the interpeduncular cistern. Traumatic SAH also commonly involves the cerebral convexity and can fill cortical sulci, which can sometimes mimic sulcal effacement¹¹⁴ (Fig. 66.9A).

Occasionally, the distribution of the hemorrhage may be hard to differentiate from an aneurysmal hemorrhage. Under this circumstance, a vascular study should be obtained (Fig. 66.9B). Cerebral vasospasm following aneurysmal SAH is a common, well-described problem with an unclear pathogenesis. Increasing evidence suggests that SAH from trauma also may cause clinically significant cerebral vasospasm, which may be responsible for ischemia and infarction.^{115,116}

Clearly the incidence of clinically relevant cerebral vasospasm is less than what is seen in aneurysmal SAH; however, posttraumatic SAH may cause ischemia during the acute as well as the delayed phase.^{115,117}

In severe nonpenetrating head injury, the degree of SAH can be predictive of outcome,^{118,119} and although traumatic SAH can be an isolated finding, it is commonly associated with other intracranial injuries.¹²⁰

Traumatic SAH can be a marker of severe primary injury and the amount of blood can also be an independent predictor of the development and progression of intraparenchymal contusions¹¹³ (Fig. 66.9C).

INTRAPARENCHYMAL CONTUSIONS AND HEMATOMAS

Traumatic parenchymal mass lesions are common and are reported in 13% to 35% of severe traumatic brain injury.¹²¹⁻¹²⁷ Contusions consist of heterogeneous areas of necrosis, pulping, infarction, hemorrhage, and edema.^{89,128,129} Hemorrhagic contusions are mixtures of blood and edematous cerebral parenchyma that also have a heterogeneous appearance on CT.⁸⁹ Contusions commonly occur in the frontal and temporal lobes both at the poles and on the inferior surfaces as a result of contact with the rough, bony skull base¹³⁰ (Fig. 66.10A).

Contusions typically involve the crests of the gyri but in more severe injury may extend into the substance of the

Figure 66.9 The patient was a 25-year-old man who sustained a brain injury in a motorcycle accident. **A**, Computed tomography (CT) scan immediately after the accident demonstrates traumatic subarachnoid hemorrhage (SAH) in cortical sulci (*thick arrow*) and anterior interhemispheric fissure (*thin arrow*). **B**, CT scan at the level of the circle of Willis reveals a distribution of subarachnoid blood (*arrow*) throughout the suprasellar cistern, a pattern similar to that seen with a ruptured aneurysm. Findings on an immediate cerebral angiogram to rule out an aneurysm were normal. **C**, Follow-up CT scan obtained 8.5 hours later demonstrates an intraparenchymal contusion (*arrow*) that was not seen on the initial study, with rapid clearing of the traumatic SAH in the suprasellar cistern.

Figure 66.10 **A**, Computed tomography (CT) scan demonstrates a typical left frontal basal contusion (*arrow*) where the brain interfaces with the rough base of the anterior cranial fossa. **B**, CT scan demonstrates left frontal (*thick arrow*) and right temporal hemorrhagic (*thin arrow*) contusions. The floor of the middle (temporal) fossa also is quite rough. This scan also illustrates the continuum from contusion to hematoma. Note the large, homogeneous areas within the contusions that could be classified as hematomas.

white matter. If the pia-arachnoid is torn, contusions are classified as cortical lacerations.¹³⁰⁻¹³²

Contusions represent one end of a spectrum of injury on which hematomas, which are well-defined, homogeneous collections of blood, are the other end (Fig. 66.10B). The amount of energy delivered may have only been enough to cause failure of small vessels, resulting in contusions. If more energy is delivered, failure of larger vessels may occur, resulting in hematomas. Alternatively, the hemorrhagic component of a contusion may continue to bleed and coalesce into a more discrete hematoma. In general, the most common traumatic parenchymal lesions are contusions,⁸⁹ and they tend to evolve.^{122,126,127,133,134}

Risk factors for the progression of intraparenchymal hemorrhage include the presence of SAH (see Fig. 66.9C), and subdural hematoma, as well as the size of the clot on the initial CT scan. Enlargement of contusions occurs approximately 40% of the time, which justifies early follow-up CT scanning.¹³⁵ In addition to the problem of progressive enlargement of existing contusions is a phenomenon of delayed appearance of traumatic intracerebral contusions (DITCH). DITCH is defined as a new contusion identified on a CT scan in an area of brain that was normal on the admission CT scan. These delayed hemorrhages are reported to occur in up to 7% of patients with severe head injuries.⁹⁰

Contusions can be subdivided into two groups. *Coup* contusions occur in the brain tissue under the impact site and

usually are associated with an acceleration injury. *Contrecoup* contusions are located away from the point of impact and usually are associated with a deceleration injury.^{130,131,136-138}

Understanding the biomechanics of how a contrecoup contusion develops is useful. In general, biologic tissues tolerate strain better if they are deformed slowly rather than quickly. For example, a 150-mL hematoma with accumulation of blood over minutes is likely to be lethal, whereas a 150-mL slow-growing meningioma may have no appreciable effect on the patient's level of consciousness. In trauma, the cause of tissue damage may be any of three types of induced strains: compression, tension, and shear. The skull, brain, and blood vessels will tolerate compression better than tension, and tension better than shear. These strains are induced by contact or inertia (relative to acceleration-deceleration), or both. Contact injuries are a result of impact, which may cause inward deformation of the skull with local effects, and of shock waves, which can produce remote effects. As a consequence of contact the head is set in motion, which leads to inertial injury. Inertial injuries may cause damage by differential acceleration of the skull and brain. In addition, acceleration-deceleration can independently produce strains in the brain itself. The two clinically relevant types of acceleration are translational (when the brain moves in a straight line) and angular. Most injuries are a combination of both.¹³⁹

These effects are best illustrated by a case example of a 37-year-old man who falls from a height onto the back of his

Figure 66.11 Computed tomography scan demonstrates a relatively small right occipital hemorrhage (*thick arrow*) underlying the point of impact as confirmed by the overlying soft tissue swelling of the scalp and a large, left frontal hemorrhagic contrecoup contusion (*thin arrow*).

head and presents with a deteriorating level of consciousness. His CT scan (Fig. 66.11) reveals soft tissue swelling at the point of impact in the right occipital region with a small underlying hemorrhage, as well as a large, hemorrhagic contusion in the left frontal lobe. The mechanism involved is primarily translational (linear) deceleration. The skull stops suddenly as it hits the ground, but the brain continues to move toward the impact site, where compression is induced (Fig. 66.12).

As the brain is moving toward the inner table of the skull at the impact site, it also is moving away from the skull on the opposite side, creating regions of low pressure and tensile strains. Contributing to the extensive tissue damage in the left frontal lobe also may be movement of the brain across the rough surface of the anterior cranial base.^{89,139}

The same amount of energy is delivered to the brain in nearly a straight line, with the compressive injury at the point of impact resulting in much less damage than the contrecoup injury caused by tension. In view of the dramatic differential susceptibilities of the brain and blood vessels to compressive and tensile strains induced in trauma, it is understandable that diffuse injuries can be caused by seemingly less violent trauma when the head undergoes an injury with a large component of angular acceleration-deceleration. This is the motion that can induce shearing strains, which the tissues tolerate poorly (see “Diffuse Axonal Injury” later on).

Surgical decision making is more straightforward for epidural and subdural types of hematomas, in which the extra-axial mass causing compression is simply on the surface of the brain. Contusions and hematomas, however, are

intra-axial masses intimately associated with surrounding regions of brain that may be salvageable. It is one thing to surgically evacuate an extra-axial hematoma *compressing* the dominant frontal lobe, and quite another to operate on a large contusion *within* the dominant frontal lobe.

In 2006, guidelines were published after a thorough review of the relevant but scientifically weak literature. The reviewers reported that patients with parenchymal mass lesions and signs of progressive neurologic deterioration referable to the lesion, medically refractory intracranial hypertension, or signs of mass effect on CT scan should be treated operatively. Patients with GCS scores of 6 to 8 with frontal or temporal contusions greater than 20 cc in volume with midline shift of at least 5 mm or cisternal compression on CT scan and patients with any lesion greater than 50 cc in volume should receive operative treatment. Patients with parenchymal mass lesions who do not show evidence of neurologic compromise, whose ICP is controlled, and who demonstrate no significant signs of mass effect on CT scan may be managed nonoperatively with intensive monitoring and serial imaging. For patients with refractory intracranial hypertension and diffuse parenchymal injury with clinical and radiographic evidence for impending transtentorial herniation, the guidelines also recommended, as treatment options, subtemporal decompression, temporal lobectomy, or hemispheric decompressive craniectomy (Fig. 66.13). With regard to timing of surgery, the literature supports a bifrontal decompressive craniectomy within 48 hours of injury as a treatment option for patients with diffuse, medically refractory posttraumatic cerebral edema and resultant intracranial hypertension.¹²⁷

HYPOTHALAMIC-PITUITARY INJURY

Injury to the pituitary and hypothalamus can complicate head injury. A prolonged loss of consciousness often is reported in patients with such injuries. Up to 80% of cases are associated with a fracture through the skull base. Injuries include (in decreasing order of frequency) pericapsular hemorrhage, hypothalamic infarction, posterior pituitary hemorrhage, anterior pituitary infarction, and rupture of the infundibulum.¹⁴⁰⁻¹⁴² Clinically measurable decreases in pituitary hormone production are not seen until at least 75% of the gland is destroyed. Complete loss of production requires destruction of at least 90% of the gland.

Derangements in pituitary function can result in decreased production of any of the pituitary hormones. Of particular clinical significance is impairment of adrenocorticotrophic hormone release that can result in secondary adrenal insufficiency (Addison's disease). Physiologic stressors such as trauma, surgery, or infection can result in Addisonian crisis, with potentially life-threatening results. Diabetes insipidus has been reported in a significant number of severe head injuries, with a high percentage of cases remaining permanent.¹⁴³ Injuries to the pituitary often are not suspected in the acute period, and the diagnosis of hypopituitarism is therefore often delayed (Fig. 66.14).

DIFFUSE AXONAL INJURY

The term *diffuse axonal injury* (DAI) describes brain damage in a group of patients who become immediately

Figure 66.12 **A**, Schematic representing the head falling in a straight line. Rapid deceleration of the skull occurs as the brain continues to move toward the impact site. The energy is applied in a linear trajectory, resulting in a compressive strain generated at the impact site and a tensile strain at the opposite point (*right diagram*). The same energy delivered to the brain results in more damage by tension than compression. **B**, A comparison of this schematic with that for a similar mechanism of injury would demonstrate why a contrecoup contusion (*arrow on computed tomography scan, left*) generally is more severe than the injury sustained as a result of compression at the point of impact.

unconscious or go into coma at the time of the head trauma.⁸¹ Depending on the severity of the injury, patients may have mild, moderate, or severe DAI. A large number of patients with severe head injury will have DAI. Because of the gradient acceleration difference of certain brain areas during primary impact, shearing forces at the gray-white junction, corpus callosum, or brainstem may occur.^{131,144} The result of these forces will be diffuse tearing of axons and small blood vessels. These lesions initially may be hemorrhagic, but as they become chronic, shrinking, softening, and scarring ensue, often with cyst formation.^{42,145} The lesions usually are microscopic but can be large and macroscopic. Although small, focal, petechial hemorrhages may be visualized, the initial CT scan often is normal.¹⁴⁶ Most of the clinical and experimental studies support that the

diffuse injury occurs at the time of initial impact and is not the result of other adverse factors, such as decreased brain oxygenation, increased ICP, or brain swelling,^{145,147} although these factors tend to accentuate the amount of damage.

The term *gliding contusions* originally was introduced by Lindenberg and Freytag¹⁴⁸ to describe hemorrhagic lesions in parasagittal white matter; this brain injury concept has been reanalyzed.¹⁴⁹ Gliding contusions frequently are found in association with DAI and acute subdural hematomas. Two mechanisms have been considered in relation to the formation of these contusions. First, during angular acceleration, more movement and displacement of the cortical gray matter occur than of the deep white matter; accordingly, most of the tissue injury occurs at the gray-white junction because shearing strains predominate. The

Figure 66.13 A 32-year-old man presented awake and alert after accidental discharge of a nail gun to the head while working at a construction site. **A, Left,** An anteroposterior radiograph of the skull demonstrates the nail. **Right,** On this intraoperative photograph, the head of the nail can be seen indenting the surface of the scalp. **B,** Preoperative bone-windowed computed tomography (CT) scan (*left*) and immediate postoperative brain-windowed CT scan (*right*) demonstrate the blood-stained tract after removal.

second mechanism involves excessive displacement of the bridging veins during brain acceleration. Patients with severe DAI who survive may be profoundly disabled, but some patients with mild or moderate DAI may recover with mild or no disability.⁸¹ The importance of recognizing DAI in the initial evaluation cannot be overstressed; this will affect the management and outcome. Clinically, these patients will have impaired consciousness secondary to bicortical damage, possibly in association with unremarkable imaging findings and normal ICP.

PENETRATING BRAIN INJURY

It is estimated that between 6000 to 7000 people die each year in the United States from gunshot wounds to the brain.^{130-139,150-152}

CLASSIFICATION

Low-velocity penetrating brain injuries include wounds from nail guns, arrows, and knives and some types of gunshot wounds (Fig. 66.15). Gunshot wounds are divided into

Figure 66.14 Computed tomography scan through the skull base in bone window demonstrating fractures through the sella turcica (arrow).

low-velocity injuries, such as from civilian handguns and shrapnel, and high-velocity injuries, from rifles and military weapons¹⁵² (see [Table 66.1](#)).

An Israeli report described an intermediate type of injury from spherical bolts whereby the ball bearings used by suicide bombers, having unique ballistics, may cause a type of “stab wound” injury to the brain.¹⁵²

BALLISTICS

The biomechanics of penetrating brain injury (PBI) are important and require an understanding of the dynamics of projectiles—that is, ballistics. Ballistics can be divided into three phases. The first phase, internal ballistics, deals with the source of the projectile and its intrinsic dynamics (e.g., rifle, bomb). External ballistics, the second phase, focuses on the flight of the projectile itself and the deviation of its longitudinal axis relative to the line of flight, referred to as yaw motion. Collision of the projectile with any object during this external phase will change the speed, angle, and yaw. The third phase is referred to as terminal ballistics, which is the physical interaction between the projectile and the body.¹⁵²

As the projectile directly crushes tissue, it forms a permanent cavity, and as surrounding tissue is compressed, a temporary cavity also is formed. As the missile breaks through

Figure 66.15 The patient was a 27-year-old man with a self-inflicted gunshot wound to the head who presented with a deteriorating level of consciousness. The patient put the muzzle of a handgun to the right medial orbital roof. The bullet traversed the frontal sinus and traveled through the left frontal lobe. **A**, Computed tomography (CT) scan demonstrates bullet fragments (*thick arrow*) and an associated left fronto-temporal acute subdural hematoma (*thin arrow*), requiring surgical evacuation and hemicraniectomy for anticipated swelling. **B**, Postoperative CT scan demonstrates edematous hemisphere herniating out through the cranial defect (*arrow*). There was damage to the anterior cranial base with contamination secondary to involvement of the frontal sinus. Surgical repair of the skull base was delayed because of the anticipated cerebral edema, and the patient was placed on antibiotics. When the cerebral swelling resolved, there was no evidence of cerebrospinal fluid (CSF) rhinorrhea or infection. The patient never required the delayed repair of the anterior cranial base anticipated. He made an excellent neurologic recovery and returned to work as a professional recruiter several months after replacement of his cranial bone flap.

the skull, secondary projectiles of bone fragments may be generated, causing independent, secondary permanent and temporary cavities.¹⁵²⁻¹⁵⁶

Terminal ballistics are influenced by many factors, such as size, shape, and stability of the penetrating object; however, most authors (but not all) believe that entrance velocity is the most important factor in determining the degree of tissue damage.^{152,153,155,157-159} Experimental evidence has demonstrated an immediate increase in ICP with a pressure wave transmitted throughout the cranial cavity, which probably accounts for the transient respiratory arrest observed in PBI.^{152,160} High-velocity injuries (velocity greater than 320 meters per second) cause shock waves that emanate from the front of the missile. These shock waves can reflect off the inside of the skull and summate, producing significant pressure gradients with remote effects.

INITIAL RESUSCITATION

Initial resuscitation in the trauma bay should be in accordance with current recommendations for head-injured patients in general. During this initial resuscitation, it is important to recognize that hypotension in PBI either is a terminal event or is related to other injuries. Once resuscitation has been accomplished, a CT scan is essential. Although skull films seldom add to the information obtained from a CT scan,¹⁵² our group has found plain films to be very helpful in PBI, particularly in industrial accidents, in which the shape of the penetrating object may be unknown.

SURGICAL MANAGEMENT

Most of what is known about the surgical management of PBI comes from the battlefield, beginning with World War I, when Harvey Cushing, the father of American neurosurgery, described his technique of en bloc craniectomy under aseptic conditions; thorough debridement of scalp, bone, brain, metal, and bone fragments; and watertight closure of the scalp. Using this management strategy a century ago, in the absence of antibiotics, Cushing reported a significant drop in postoperative mortality from 55% to 28%.^{161,162}

Mortality decreased even further in World War II, primarily because neurosurgical personnel were present in forward military hospitals and antibiotics were introduced. The operative approach, however, was largely the same: that of radical debridement. Treatment consisted of four tiers: emergent life-saving maneuvers through hemostasis and cerebral decompression; prevention of infection through extensive debridement; preservation of nervous tissue through prevention of meningocerebral scars; and restoration of anatomic structures through accurate closure of the dura and scalp. Although untested against other management strategies, this approach became the standard of treatment for PBI by default. Indeed, in the U.S. military, thorough debridement of intracranial bone and metal fragments was official military policy through the Vietnam War.¹⁶²

The overall mortality rate from PBI sustained during relatively modern wartime conditions ranges from 8% to 43% and generally is considered to be in the 20% range.¹⁶²⁻¹⁷¹ The mortality rate from military gunshot wounds has been reported to be 2.5 to 4 times more than from shrapnel.^{162-165,170} Of interest, mortality rates from wartime PBIs in the U.S. military from World War II through the Vietnam War did not change significantly,¹⁷² which is consistent with the

relatively unchanged management strategy of complete removal of intracranial bone or metal fragments, using repeated surgery as necessary.¹⁷³

Aggressive debridement was intended to reduce complications such as infection, epilepsy, and cerebral edema. However, studies reveal that additional surgery to remove retained fragments results in significant morbidity and mortality.^{170,174,175}

The use of broad-spectrum antibiotics in recent wars has resulted in data suggesting that retained bone fragments are not independently associated with an increased risk of infection. Therefore, aggressive debridement is no longer supported.^{162,176} The use of broad-spectrum antibiotics in PBI has now become universal.¹⁵²

Multiple studies have looked at post-PBI epilepsy and reported an incidence of 22% to 53%.^{167,177,178} Several studies suggest that it is not necessary to remove all bone fragments in order to decrease the chance of developing epilepsy, but the value of removing metal fragments in this regard remains unclear.^{162,167,169,177,178} In military PBI, it appears that vigorous debridement is associated with increased morbidity and mortality and is not necessary to prevent infection, has no obvious efficacy in preventing epilepsy, and does not appear to improve survival.¹⁶²

A CSF leak resulting from a PBI is the variable most highly correlated with intracranial infection.* One study found that most CSF leaks appeared within 2 weeks of the injury and less than half of them closed spontaneously. The incidence of infection was approximately 10 times higher in the group with CSF fistulas than in the group without leaks, and the mortality was greater as well.¹⁸¹ Because CSF leaks are the primary predictor of the development of intracranial infection,^{167,169,171} it is important to fix or prevent a CSF leak; therefore, a watertight closure of the scalp entry wound is necessary.¹⁸¹

To accomplish this objective, various surgical interventions are available. Small entrance wounds without underlying surgical pathology may be cleaned up and closed in the emergency department.¹⁸² Complex entry wounds or those with underlying surgical pathology will require more extensive surgical manipulation, which may include extending the incision to allow vigorous superficial debridement; complete excision of devitalized tissues including muscle, fascia, and periosteum; extension and debridement of the bony entry or exit site by craniectomy; and similarly generous debridement of the dural opening with watertight closure, using grafting as necessary.[†]

PREDICTIVE FACTORS

Increased mortality in penetrating head injury is associated with increasing age, suicide attempts, hypotension, coagulopathy (particularly with lower GCS scores), respiratory distress, low GCS score, bilateral fixed and dilated pupils, high ICP, and cisternal effacement on CT scan. Mortality also is increased with traumatic injuries in which a missile tract perforates the skull (through-and-through injury) or with injuries that involve both hemispheres, multiple lobes, or the ventricular system.¹⁶²

In civilian gunshot wounds to the head, a specific vector analysis from Los Angeles County demonstrated a region of

*See references 162, 166, 167, 170, 179-182.

†See references 161, 168, 170, 172, 183, 184.

involvement that resulted in 100% fatality and is designated as the zona fatalis. This region comprises the midbody of the ventricle, the body of the corpus callosum, and the cingulum.¹⁸⁴

No effect has been demonstrated for weapon caliber on outcome, independent of total kinetic energy, and no relation between midline shift and outcome has been established.¹⁶²

SPECIAL PROBLEMS

Special problems that may be encountered with PBI include those associated with craniofacial entrance wounds: an increased incidence of hematoma formation, direct vascular injury, extensive contamination due to paranasal sinus involvement (see Fig. 66.15), and CSF fistulas.¹⁵²

Other special problems include dural venous sinus involvement, tangential wounds, and traumatic aneurysms, with 0.4% to 0.7% of all intracranial aneurysms being caused by penetrating trauma.¹⁸⁵

In PBI, mechanical loading of the cerebral vasculature, by either the contact forces of the projectile or the shearing forces of a pulsating temporary cavity, may cause partial or complete transection of an arterial wall. Such damage can result in SAH or formation of intracerebral and intraventricular hematomas.^{162,186,187}

Damage to the arterial wall also may cause the development of a traumatic intracranial aneurysm (TICA). TICAs are primarily false aneurysms, which could heal or change in size over time, but they are especially vulnerable to rupture and can lead to delayed traumatic intracerebral hematoma or SAH or both.^{185,188-190}

Patients with an increased risk of vascular injury include cases in which the trajectory passes through or near the sylvian fissure, supraclinoid carotid, cavernous sinus, or a major venous sinus. The development of substantial and otherwise unexplained SAH or delayed hematoma also should prompt consideration of a vascular injury.¹⁶²

Cerebral angiography (CTA or conventional) remains the usual technique to detect intracranial aneurysms.^{187,189,191} Because a majority of traumatic intracranial aneurysms are not true aneurysms, excluding the aneurysm by clipping may not be possible and may require trapping between clips on the parent vessel.¹⁶²

COURSE IN THE INTENSIVE CARE UNIT

Not surprisingly, intracranial hypertension is common after PBI.^{181,192-194} Early ICP monitoring should be considered when the ICU clinician is unable to assess the patient's neurologic status accurately; if the need to evacuate a mass lesion is unclear; or if CT scanning suggests elevated ICP.¹⁶² Another practical use for ICP monitoring is ongoing assessment of a patient with a depressed level of consciousness to look for an early sign of progressive intracranial pathology, which may require repeated imaging and surgical decompression.^{181,192,194}

Cerebral autoregulation may be defective after PBI^{181,192,194}; cerebral edema can appear extremely rapidly, contributing to medically refractory intracranial hypertension. Systemic hypertension may exacerbate intracranial hypertension after PBI.¹⁶²

Treatment is not necessarily futile, and some patients with intracranial hypertension can be managed successfully and

survive with acceptable morbidity.^{181,192,194,195} However, the literature does not clearly relate successful treatment of intracranial hypertension after PBI to an improved outcome. Not enough good data are available to guide management strategies for intracranial hypertension after PBI. It cannot be assumed that the intracranial pathology is the same as in nonpenetrating traumatic brain injury. Because of the paucity of data, however, treatment generally follows the methods for nonpenetrating traumatic brain injury as outlined in Guidelines for the Management of Severe Traumatic Brain Injury.^{162,196}

Harrington and Apostolides have proposed a treatment algorithm for patients with gunshot wounds to the head. Patients who have lesions causing mass effect and a postresuscitation GCS score of 7 or greater undergo surgery, and patients with a GCS score of 3 or 4 with bilaterally fixed pupils after resuscitation receive no treatment beyond wound closure. In patients with GCS scores of 5 or 6, treatment should be individualized, depending on pupillary findings and other conditions.¹⁹⁷

SECONDARY HEAD INJURY

BASIC CONCEPTS

Management of primary head injury generally entails the surgical management of head-injured patients and typically is driven by the presence of pathologic masses (hematomas) in anatomic spaces. Management of secondary head injury usually involves the nonsurgical management of these patients and deals with the pathologic derangement of physiologic processes.

The three functional volumetric compartments in the head are blood, brain, and CSF. The volumes of these three functional compartments are approximately 1200 mL for brain, 150 mL for CSF, and roughly 150 mL for the variable blood compartment. The total volume of the intracranial compartment is relatively fixed and relatively incompressible. Therefore, if volume is added to one of these three compartments, a compensatory loss of volume from another compartment will occur; otherwise, ICP will rise. To illustrate this point, a pressure-volume curve for the intracranial compartment is shown in Figure 66.16. Initially, as volume is added to the system, no significant change in pressure occurs. With cerebral edema, for example, as the brain compartment increases in volume, venous capacitance vessels collapse, which moves blood volume out of the system; therefore, overall net volume does not change and ICP remains stable. As the brain continues to swell and increase in volume, the ventricles become smaller as CSF moves out of the system, again keeping overall net volume and ICP relatively stable. At some point the system loses this buffering capacity, and as more injury-related volume accumulates, ICP starts to rise. The rise in ICP is gradual, progressive, and nonlinear. As the system continues to get stressed with additional volume, it progressively loses compliance and, in effect, gets stiffer. The result is that increasingly smaller volumes introduced into the system result in higher changes in ICP. Using MRI methods to study cerebral edema, Marmarou and colleagues noted a rise in ICP when edema was only 1% higher than the normal water content

Figure 66.16 Pressure-volume curve of the intracranial compartment using cerebral edema as an example (see text). The computed tomography (CT) scan above the graph on the *left* is an image of a normal brain. The CT scan on the *right* demonstrates severe cerebral edema in a trauma patient with obliteration of most of the subarachnoid space, reducing cerebrospinal fluid (CSF) volume to make room for the swelling brain. Initially, as CSF moves out of the system, overall net volume does not change significantly. This part of the process is represented by the flat part of the curve toward the *left* and reflects the buffering capacity of the brain to respond to gradual increases in volume.

of brain tissue. These investigators also showed that when water content increased in a contused hemisphere, ICP increased exponentially. These findings demonstrate the importance of small changes in intracranial volume, particularly when the buffering capacity of the system has been exhausted.¹⁹⁸

Increased ICP may be associated with mass effect secondary to unbalanced forces, causing direct, mechanical compressive damage to involved structures. This condition generally necessitates surgical decompression in the operating room. Increased ICP also may result in inadequate perfusion. This condition generally requires medical management in the ICU (Fig. 66.17).

The heart delivers blood at a given mean arterial blood pressure (MABP), the systemic perfusion pressure, to the base of the skull. The blood pressure then has to overcome whatever pressure is inside the head for blood flow to get in, and whatever is left over will be the pressure that perfuses the brain—that is, cerebral perfusion pressure (CPP). Simple in concept and calculation, CPP is defined as the mean arterial blood pressure minus ICP ($CPP = MABP - ICP$). It is the physiologic variable that defines the pressure gradient driving cerebral blood flow (CBF) and metabolic delivery and is therefore closely related to ischemia.^{199,200}

Technically, the MABP should be measured as the mean carotid pressure with the arterial line transducer zeroed at

the level of the foramen of Monro (as opposed to the right atrium),²⁰¹ but this approach is not common in clinical practice. Normal values generally are considered to be 60 to 80 mm Hg for CPP and approximately 10 mm Hg or less for ICP.

The ultimate cause of secondary injury is typically ischemic, and the fundamental goal in dealing with severe traumatic brain injury is to ensure adequate CBF relative to the metabolic demand of the brain. It is, however, impractical to continuously measure CBF at the bedside. Fortunately, CBF is dependent on CPP—which can easily and continuously be measured at bedside. Therefore, a fundamental management strategy for treating a head-injured patient is to maintain adequate CPP by lowering ICP, accomplished by reducing intracranial volume.

Surgical methods for reducing intracranial volume include evacuating an intracranial hematoma, removing part of the frontal or temporal lobe, and placing a ventriculostomy to drain CSF. Other methods for reducing intracranial volume are applicable in the ICU setting, where management strategies are directed at treating volume in the blood and brain compartments.

CEREBRAL BLOOD VOLUME

In discussing cerebral blood volume, it is useful to divide this topic into the arterial and venous compartments.

Figure 66.17 **A**, Increased intracranial pressure can be associated with unbalanced forces causing mass effect, shift, and possibly herniation. The resultant pathostructural changes from such unbalanced forces (arrows) usually are managed surgically. With increased intracranial pressure, cerebral perfusion may be impaired, resulting in ischemia—the ultimate secondary injury. Intractable intracranial hypertension and inadequate perfusion can lead to brain death, as demonstrated by the nuclear flow study shown in **B**. Note the absence of flow to the brain (thick arrow), compared with the overly generous blood supply to the face, sometimes referred to as the “hot nose sign” (thin arrow).

ARTERIAL BLOOD COMPARTMENT

Blood Pressure

Systemic blood pressure has a direct effect on arterial cerebral blood volume. Normally, CBF will remain relatively constant over a wide range of perfusion pressures as cerebrovascular resistance (CVR) automatically adjusts. The autoregulation curve (Fig. 66.18) demonstrates the relationship among CBF, perfusion pressure, and cerebrovascular resistance. As MABP goes up, CVR increases in order to maintain a stable CBF.

The CVR increases by vasoconstriction, which reduces the volume of blood in the brain. Conversely, as MABP drops, CVR goes down by means of vasodilation, which increases the volume of blood in the brain. This is a very powerful system; a cerebral arteriole has the ability to change its diameter by up to 200%. It also is quite fast, responding to sudden changes in pressure within 3 to 5 seconds.

Most people have had the experience of suddenly jumping out of bed after having been recumbent for several hours and then feeling the “lights going out” as the cerebral vasculature rapidly dilates in response to the sudden drop in perfusion pressure and CBF; after several seconds, the lights come back on as cerebrovascular status is restored, as reflected by flattening of the autoregulation curve.

A normal MABP for a young, healthy adult is approximately between 70 and 90 mm Hg, and a normal ICP generally is considered to be approximately 10 mm Hg or less, which is consistent with a normal range of CPP values between 60 and 80 mm Hg. Although the normal ranges are at the low end of the autoregulation curve, there is the ability to autoregulate between perfusion pressures ranging from 50 to 150 mm Hg. It is clear from the autoregulation curve that CBF becomes a direct, linear function of MABP when outside the ability of the cerebrovascular bed to

maximally dilate (MABP less than 50 mm Hg) or constrict (MABP greater than 150 mm Hg).

The normal range of 50 to 150 mm Hg is not rigidly fixed, and individual variations are common. A hypotensive patient with an MABP of 20 mm Hg clearly is in shock, but what about a 21-year-old athlete who has just had surgery for a ruptured appendix with an MABP of 45 mm Hg? Clearly a clinical assessment is necessary in borderline situations, and one of the most important indicators of shock is a change in mental status. In this example, if the athlete demonstrates a change in mental status, he is likely to be off his autoregulation curve and in shock.

At the other end of the spectrum is systemic hypertension. Is a 74-year-old patient with longstanding hypertension who presents with an MABP exceeding 150 mm Hg by a few points having a hypertensive crisis? Again, a change in mental status may be the indicator that autoregulatory capacity has been exceeded, and the patient may be diagnosed with hypertensive encephalopathy.

CVR often is increased by trauma. At the beginning of the autoregulation curve, CBF is zero at a perfusion pressure greater than zero. A measurable pressure in the vessel exists, yet no blood flow occurs, indicating vascular collapse (see Fig. 66.18). The cerebrovasculature in its resting state is collapsed; it takes a certain amount of energy (pressure) to open the vessels. These vessels each have critical opening and closing pressures. After a head injury, free radicals can be released, which tend to make biologic tissues less compliant. This in turn may make it more difficult for the vessels to stay open—that is, more pressure is required to keep the vessels from closing, which could shift the autoregulation curve to the right (see Fig. 66.18).²⁰²⁻²⁰⁵ This is the theoretical basis for the studies that led to the earlier recommendations to keep the minimum CPP in head-injured patients above normal values—that is, at 70 mm Hg or greater.²⁰⁶

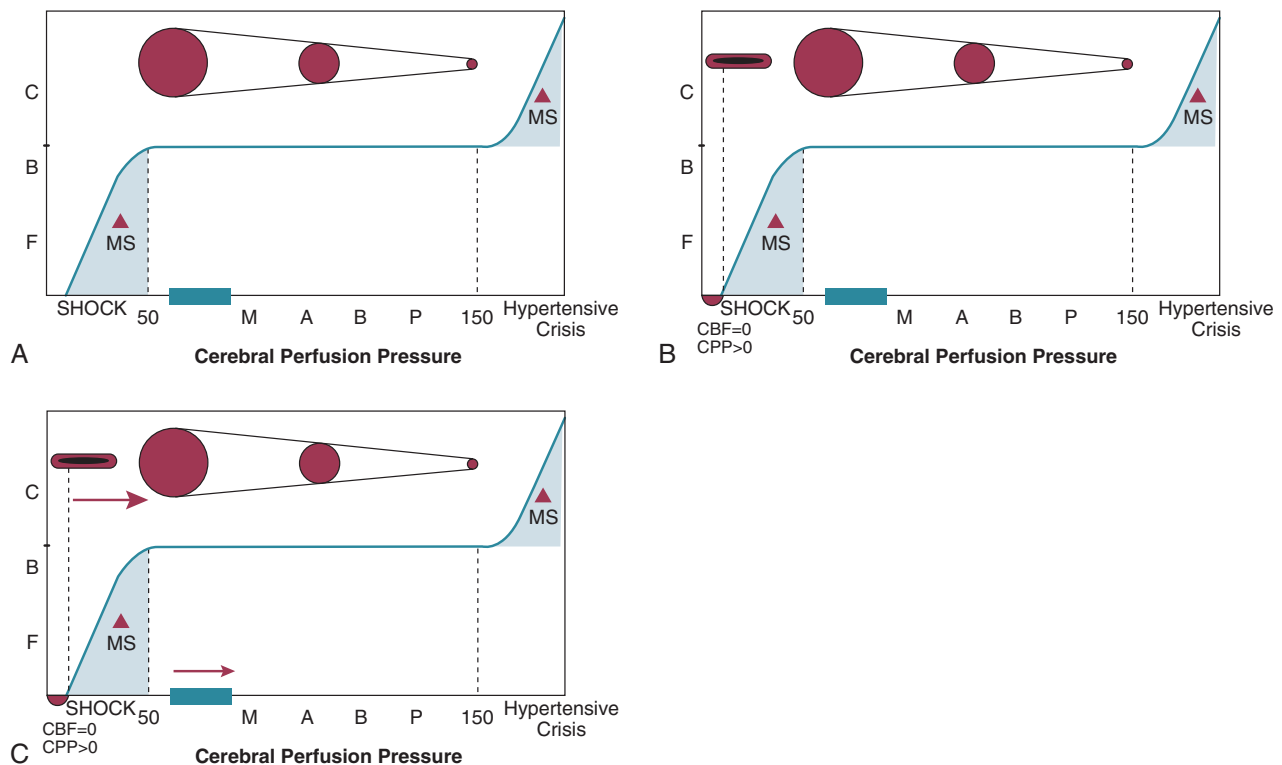

Figure 66.18 **A**, The autoregulation curve demonstrates how the brain maintains a relatively constant CBF over a wide range of perfusion pressures by changing the caliber (resistance) of the cerebral vasculature, which necessarily leads to changes in intracranial volume. Under normal circumstances, when ICP is negligible, the MABP is equivalent to CPP; however, when ICP is elevated, it is the CPP that is “read” by the brain. CPP will drive CBF, causing changes in cerebrovascular resistance, unless overridden by other superimposed processes such as hyperventilation, which may be pathologic or intentionally altered for a therapeutic effect. Although we have the ability to autoregulate over a wide range of perfusion pressures, the normal range is at the lower end of the curve (*horizontal green bar*). **B**, The normal resting state of the cerebrovasculature is collapsed. These vessels have critical opening and closing pressures that are slightly different from each other. With the vessel open, it typically will collapse at a slightly lower pressure than is required to open it from a collapsed state. **C**, After a significant injury, the potential exists to increase the critical closing pressure, which could shift the autoregulation curve to the right. CBF, cerebral blood flow; CPP, cerebral perfusion pressure; MABP, mean arterial blood pressure; MS, mental status.

Cerebral Perfusion Pressure

A low perfusion pressure jeopardizes ischemic regions of the brain. Increasing intravascular hydrostatic pressure by increasing CPP can help improve cerebral perfusion. Although CPP can be manipulated and enhancement of CPP may help to avoid both global and regional ischemia, the level at which CPP is best maintained is not entirely clear,²⁰⁶ and considerable interest has been directed toward attempts to determine the optimum CPP for a head-injured patient. Some studies suggest that increasing CPP to greater than 70 mm Hg leads to improved outcomes.²⁰⁷

A combination of studies of traumatic brain injury in which CPP was actively maintained at approximately 70 mm Hg in patients with a GCS score less than 8 reported a mean mortality rate of 21%, which was substantially less than the 40% mortality rate reported for similar patients in the Traumatic Coma Data Bank (TCDB). Good recovery and moderate disability rates were 54% in the patients whose CPP values were maintained in the 70 mm Hg range, compared with the 37% reported in the TCDB. However, it could not be concluded that the improved outcomes in these studies were a result of CPP management because none of the reported studies was a randomized, prospective trial of this treatment^{200,205,208-212}; and in some, another treatment was actually the focus of the study.^{208,209}

In a prospective study of 21 patients with severe traumatic brain injury in whom brain tissue PO_2 ($BtiO_2$) was monitored, ischemic episodes during the first week after injury were associated with unfavorable neurologic outcomes. Elevation of the CPP improved $BtiO_2$, but raising CPP above 68 mm Hg did not cause a further increase in $BtiO_2$. In the investigators’ analysis, a CPP greater than 60 mm Hg emerged as the most important factor determining a sufficient $BtiO_2$.^{200,213}

Another prospective, controlled trial of 189 adult patients with a motor GCS score of 5 or lower within 12 hours of head injury randomized patients to an “ICP-targeted protocol” in which CPP was kept above 50 mm Hg or to a “CBF-targeted protocol” in which CPP was kept above 70 mm Hg. The investigators in this study found no significant difference in outcome. In this trial, the mean CPP for patients managed in the CBF-targeted protocol was 76 mm Hg and for those in the ICP-targeted protocol, 72 mm Hg. These differences were small but statistically significant.²¹⁴

Contant and associates used data from this trial to examine risk factors for acute respiratory distress syndrome (ARDS) and consequences of its development. The risk of ARDS was five times greater among patients in the CBF-targeted group than in those in the ICP-targeted group and was associated with a more frequent use of epinephrine and a higher dose

of dopamine.^{199,215} Patients in whom ARDS developed were two and a half times more likely to develop refractory intracranial hypertension²¹⁵ and almost three times more likely to be in a vegetative state or dead at 6 months after injury.^{215,216} These outcomes may be a direct consequence of ARDS, and the related therapeutic limitations of treating raised ICP and low CPP in the presence of ARDS.¹⁹⁹

Analysis of data from a study investigating the value of a neuroprotective agent in 427 patients with severe traumatic brain injury revealed that the critical CPP threshold was 60 mm Hg. Although CPPs that were persistently less than 60 mm Hg were associated with a significant decline in outcomes, no effect on neurologic outcomes was observed for patients who had CPPs that were higher, and specifically no difference was observed among those who averaged 60 mm Hg and those at 70 mm Hg or higher.^{199,217}

In 1995 and 2000, the Brain Trauma Foundation in cooperation with the American Association of Neurological Surgeons and the Joint Section for Trauma and Critical Care published guidelines for the management of severe head injury. From the data available, based on the theoretical need to increase the minimum CPP because of a change in critical closing pressures (see Fig. 66.18), the guidelines recommended maintaining a minimum CPP of 70 mm Hg or greater—10 mm Hg above the accepted norm. In 2003, this group updated the recommendation for CPP management and published a guideline that CPP should be maintained at a minimum of 60 mm Hg. In the absence of cerebral ischemia, aggressive attempts to maintain CPP above 70 mm Hg with fluids and pressors should be avoided because of the risk of ARDS.¹⁹⁹ In 2007, the recommendations were again modified with a level 3 recommendation to target CPP values within the range of 50 to 70 mm Hg.²⁰⁰ Clearly, guidelines change as new data become available and the reader is strongly advised to check for the most up-to-date recommendations.

CARBON DIOXIDE

Carbon dioxide is a powerful regulator of cerebrovascular resistance. At any given physiologic perfusion pressure, P_{aCO_2} can act rapidly and severely to affect CBF in a linear fashion by vasodilating or vasoconstricting the cerebrovascular bed. For every mm Hg change in P_{aCO_2} , a 3% change in CBF can occur.²¹⁸

Allowing the P_{aCO_2} to rise to levels between 60 and 80 mm Hg can result in a doubling of CBF, through vasodilation with a concomitant increase in cerebral blood volume (CBV). Conversely, aggressive hyperventilation of a patient down to a P_{aCO_2} of 20 mm Hg or less can result in CBFs being cut in half, along with a reduction in CBV. Hyperventilation was a mainstay in the therapeutic management strategy of treating head-injured patients because it had such immediate and measurable effects on ICP. Lowering P_{aCO_2} causes rapid vasoconstriction, resulting in reduced CBV, which translates to reduced intracranial volume, which lowers ICP and increases CPP. However, hyperventilation reduces ICP by taking blood *away* from the brain, when the goal is to prevent ischemia. As seen on the autoregulation curve, the cerebrovasculature is fine-tuned to the existing perfusion pressure, providing a normal level of CBF. Aggressive hyperventilation can override the normal effect of

MABP and cause a marked increase in CVR to the point at which a very high perfusion pressure would be needed to match the degree of severe vasoconstriction induced in order to maintain a normal level of CBF. This is the mechanism involved when a normal person hyperventilates, vasoconstricts, and becomes lightheaded as CBF falls. It is important to recognize that this individual has a normal MABP, ICP, and CBF before the P_{aCO_2} decreases.

Despite the fact that hyperventilation lowers ICP, the degree of vasoconstriction can be disproportionate relative to the enhancement in CPP. For example, at an MABP of 80 mm Hg with an ICP of 30 mm Hg and a CPP of 50 mm Hg, aggressive hyperventilation could reduce ICP to 15 by reducing intracranial volume, thereby improving CPP to 65. But aggressive hyperventilation can cause severe vasoconstriction. At maximal vasoconstriction, the cerebrovascular bed would need an MABP of 150 mm Hg with a normal ICP in order to maintain a normal CBF.

The data on CBF in severely head-injured patients indicate that phases of CBF change over time after traumatic brain injury, with hypoperfusion occurring in the first 24 hours.²¹⁸ Multiple studies have identified brain ischemia in up to 35% of serious head injuries within the first 12 hours.^{200,218-224} It appears that this reduction happens almost immediately. Mean CBF values measured less than 4 hours after head injury in adults were 32 mL/100 g/minute in survivors and 20 mL per 100 g per minute in nonsurvivors (normal CBF is 55 mL/100 g/minute).²²⁴ Low cerebral blood flow, to ischemic levels (less than 18 mL/100 g/minute), was observed in 31% of patients with severe head injury measured an average of 3 hours after trauma.^{200,225}

Because of the consistent data regarding reduced CBF early after trauma, attempts at further reductions using hyperventilation have come under close scrutiny. Some evidence suggests that hyperventilation carries a particular risk of causing cerebral hypoxia when P_{aCO_2} is 30 mm Hg or less, or within the first 24 hours^{226,227} because of a further reduction of an already low CBF.²²⁵ It has become clear that hyperventilation decreases B_{tiO_2} because of decreased CBF in most patients, which negates the perceived benefit of improving intracranial and cerebral perfusion pressures.^{213,226,227-232}

On the basis of principles reflecting a high degree of clinical certainty, the Brain Trauma Foundation (BTF) in 1995 and 2000 recommended that in the absence of increased ICP, chronic prolonged hyperventilation therapy (P_{co_2} of 25 mm Hg or less) should be avoided after severe traumatic brain injury.²³³

On the basis of principles reflecting a moderate degree of clinical certainty, this group recommended that the use of prophylactic hyperventilation (P_{co_2} less than 35 mm Hg) therapy during the first 24 hours after severe traumatic brain injury should be avoided because it can compromise cerebral perfusion during a time when CBF is reduced. On the basis of principles for which there is unclear clinical certainty, the group recommended that hyperventilation therapy may be necessary for brief periods during acute neurologic deterioration, or for longer periods in the presence of intracranial hypertension refractory to sedation, paralysis, CSF drainage, and osmotic diuretics.²³⁴

Figure 66.19 Graph demonstrating the relationship of cerebral blood flow (CBF) to oxygen (P_{O_2}). Within a physiologic range, oxygen is of no use as a therapeutic tool. The cerebral vasculature will vasodilate under hypoxic conditions, so hypoxia must be avoided.

OXYGEN

Within a normal physiologic range, oxygen causes little or no change in CBF (Fig. 66.19). Beyond a P_{aO_2} of approximately 300 mm Hg, CBF can begin to wane. Oxygenation does become very important at P_{aO_2} levels considered to be hypoxic. Below a P_{aO_2} of 60 mm Hg in most head-injured patients, the cerebrovasculature can vasodilate rapidly, causing an increase in CBV with poorly oxygenated blood, with an attendant increase in intracranial volume and pressure.

With careful clinical monitoring, our group has observed ICP spikes as a result of acute oxygen desaturation before a change in the pulse oximeter reading. With a moderate degree of clinical certainty, the BTF has recommended that hypoxia, defined as apnea or cyanosis in the field or a P_{aO_2} less than 60 mm Hg, must be scrupulously avoided or corrected immediately. Therefore, in contrast with P_{aCO_2} , manipulation of P_{aO_2} is not a useful tool for medical management of a head-injured patient, and hypoxia must be avoided.²⁰⁰

In view of the powerful effects of hypoxia and hypercarbia, it is no surprise that early intubation in significant head injury is important.

METABOLISM

Under normal circumstances, the cerebral metabolic rate of oxygen ($CMRO_2$) is directly related to CBF; this is referred to as a coupled relationship. As metabolic demand increases, the cerebrovasculature will vasodilate to supply an appropriate increase in CBF; and, conversely as $CMRO_2$ decreases, the cerebrovasculature will vasoconstrict to maintain a coupled relationship between supply and demand. As demand exceeds supply and the ability of the brain to extract more oxygen wanes, ischemia develops. Therefore, whatever increases the $CMRO_2$ will cause an appropriate vasodilatory response in the brain with its attendant increase in CBV and, potentially, ICP, with a resultant decrease in CPP. Clearly, if the primary event is an increase in demand and the end result is a reduction in supply, the gap between supply and demand increases, and with it the potential for ischemia. Under physiologic conditions whereby the $CMRO_2$ is coupled to CBF, various clinical states will demonstrate an appropriate balance of the two. For example, a comatose patient will have low $CMRO_2$, and a patient having a generalized seizure will have a high $CMRO_2$.

The metabolic state of the brain is sensitive to changes in temperature; lower temperatures lower $CMRO_2$, and vice versa. Recognition of this relationship has led to interest in using hypothermia as a therapeutic tool in severe head injury, both as a way to lower ICP and as a neuroprotective strategy by reducing demand in the face of limited supply. Although hypothermia can be a useful adjunct to standard treatments for controlling elevated ICP it is difficult to find good data to prove a benefit in outcome. Clifton and associates found that ICP was lower in patients managed with hypothermia, but no improvement in outcome was observed, and the complication rate was higher than in a normothermic group. These investigators concluded that lowering body temperature to 33° C within 8 hours after injury was not effective in improving outcomes in patients with brain injuries.²³⁵ A Cochrane review of therapeutic hypothermia for head injury looked at 14 trials with more than 1000 participants and found no evidence that hypothermia is beneficial in the treatment of head injury, and that it increased the risk of pneumonia nearly twofold.²³⁶ A different meta-analysis using clinical trials of moderate or poor quality, identified preliminary findings suggesting a greater decrease in mortality risk when target temperatures are maintained for more than 48 hours, as well as an association with better outcomes.^{237,238}

Although it is not clear that routine use of prophylactic hypothermia is helpful, hyperthermia is believed to be harmful to a severely head-injured patient.²³⁹ As the temperature rises, so does the $CMRO_2$, with a concomitant increase in CBV. If the patient has lost enough compliance then small changes in intracranial volume can result in big changes in ICP (see Fig. 66.16), and CPP can fall.

A frequent scenario is development of a fever in a trauma patient with a high ICP and poor compliance who is barely meeting metabolic needs. Metabolic requirements increase as CBV and ICP increase and CPP decreases, widening the gap between supply and demand, resulting in ischemia.

Another consideration in the management of $CMRO_2$ is drug effect. Pentobarbital is the gold standard drug for reducing cerebral metabolism and can be used in cases of refractory intracranial hypertension to induce a barbiturate coma. A condition of burst suppression is achieved, meaning that the continuous EEG recording demonstrates periods of an isoelectric tracing (straight line) interrupted by bursts of cortical electrical activity. This therapy results in vasoconstriction appropriate for the degree of reduction in metabolism, with an attendant decrease in ICP. This has the theoretical advantage of improving supply to a brain with reduced metabolic demands. However, despite the evidence for cerebral protection in experimental models, little clinical evidence is available to suggest that barbiturates improve outcome after severe head injuries in humans. Other drugs that reduce the $CMRO_2$ and CBF are other barbiturates such as thiopental, as well as the substituted phenol propofol, the hypnotic agent etomidate, and the water-soluble short-acting benzodiazepine midazolam.²³⁹

VISCOSITY

When autoregulation is intact, lowering viscosity of the blood improves flow dynamics and results in an appropriate increase in CVR to maintain a constant, normal CBF.²⁴⁰⁻²⁴⁴

This vasoconstriction reduces intracranial volume. From a rheologic standpoint, there is an advantage to lowering viscosity by hemodilution, but this is at the expense of oxygen-carrying capacity. Reducing the hematocrit from 45% to 30% can theoretically double CBF, yet oxygen-carrying capacity would be reduced by only a third. By generalizing experimental and clinical data involving ischemia and hematocrit, it is reasonable to consider an optimum hematocrit of approximately 30% to 35%.²⁴⁵

A common mechanism for lowering viscosity in traumatic head injury is the use of mannitol, which causes an immediate influx of extravascular water, leading to hemodilution. The vasoconstriction resulting from this reduction in viscosity allows the same CBF and oxygen delivery to be maintained by means of smaller vessels and with a lower intracranial volume (see later section, “[Hyperosmolar Therapy](#)”). In addition, mannitol will dehydrate the red blood cells themselves by about 15%, which further improves blood flow dynamics.²⁴⁵

VENOUS BLOOD COMPARTMENT

In general, vascular organization of most organ systems is anatomically similar—for example, the renal artery travels with the renal vein. The brain, however, has two entirely different anatomic systems for arterial supply and venous drainage. The paired carotid and vertebral arteries provide the arterial supply to the brain but have no corresponding venous counterparts. Blood leaves the brain through cortical and deep draining veins that empty into the superior sagittal, transverse, and sigmoid sinuses. These dural sinuses are open, semirigid structures that empty into bilateral jugular veins, which communicate directly with the right heart through the superior vena cava. There are no valves in this entire venous system. This means that right heart pressures are in direct continuity with the superior sagittal sinus within the intracranial compartment. When measured with the subject lying supine, ICP cannot be lower than central venous pressure. Of more importance, right heart pressures will be directly transmitted to the intracranial compartment, a relevant dynamic involved with a Valsalva maneuver.

During a Valsalva maneuver, intrathoracic pressure elevates and venous return to the right heart goes down. Decreased venous return means decreased venous outflow from the brain. This results in a rapid, instantaneous increase in CBV as the arterial side continues to supply the brain with blood that is not getting physiologic draining. A Valsalva maneuver also will decrease cardiac output along with a decrease in venous return, but it is a disproportionate change. A common neurosurgical practice is to have the anesthesiologist induce a controlled Valsalva maneuver toward the end of a brain operation during the final stages of hemostasis, just before beginning the closure. Intrathoracic pressure is elevated to approximately 30 mm Hg for 10 seconds as the surgeon looks for any areas of bleeding while the brain immediately physically and visibly swells as it engorges with blood. An intrathoracic pressure of 30 mm Hg will overcome a normal CVP and essentially interrupt venous outflow from the brain. The concomitant decrease in cardiac output with a pressure of 30 mm Hg will have much less of an effect than on the venous side; therefore, a relatively large volume of arterial blood will continue

to fill the brain. Even a normal brain with normal compliance will immediately “feel” the effect of decreased venous outflow because it happens faster than the buffering capacity of the brain can handle (see [Fig. 66.16](#)). In fact, one mechanism the brain will use to buffer increases in volume is to collapse venous capacitance vessels, which, in the case of decreased venous outflow from the brain, becomes part of the problem, not the solution.

Other common ways in which venous outflow from the brain can be compromised is with anything that interferes with jugular venous drainage such as a tight-fitting rigid cervical collar or thrombosis from an internal jugular line. It is not uncommon to have dominant venous outflow on one side and, following head rotation to that side, increased resistance to venous outflow. Obviously, gravity also will have a role, with head elevation enhancing venous outflow from the brain. We generally keep our patients with the head elevated at 30 degrees, with neck straight and free of lines, with a good-fitting cervical collar that is not too tight.

BRAIN COMPARTMENT

Another functional volumetric compartment is the brain itself. One of the consequences of traumatic brain injury is an acute increase in total brain water.²⁴⁶

The volume of the brain parenchyma can be affected by therapeutic dehydration induced with the use of osmotic agents. These agents can be used to treat cerebral edema in an effort to remove a pathologic accumulation of fluid. Dehydration also can be used to manipulate the volume status of an otherwise normal but threatened brain compartment in order to emergently manage an increase in ICP as a temporizing measure before surgery, such as with extra-axial hematoma or hydrocephalus. The agents most commonly used to effect these changes are mannitol and hypertonic saline.

CEREBRAL EDEMA

By definition, brain edema is an abnormal accumulation of fluid within the brain parenchyma that produces a volumetric enlargement of the brain tissue.¹⁹⁸ The three types of cerebral edema are vasogenic, neurotoxic, and cytotoxic. Vasogenic edema occurs when the blood-brain barrier opens, resulting in movement of vascular fluid into the extracellular spaces of the brain.²⁴⁷ Neurotoxic edema involves astrocytic and dendritic swelling secondary to the neurotoxic effects of excitatory amino acids, particularly glutamate, seen with reperfusion.¹⁹⁸ Cytotoxic edema results from retention of water within swollen cells, most commonly found in stroke, in which interruption of energy supply leads to pump failure and an intracellular increase in sodium and water.¹⁹⁸

It is ischemia, associated with energy failure at the level of mitochondria, that contributes to cytotoxic brain edema and intracranial hypertension.²⁴⁶⁻²⁵⁴ Earlier studies led to the general acceptance that traumatic brain swelling was primarily a result of vascular engorgement, which caused increased ICP.²⁵⁵⁻²⁵⁹ Although opinions differ, more recent work has demonstrated that cerebral edema may be primarily responsible for brain swelling, not vascular engorgement.^{251,260} Marmarou and colleagues have used sophisticated MRI techniques to demonstrate that traumatic brain edema

is predominantly a cellular phenomenon in both focal and diffuse brain injury.¹⁹⁸

Although cellular edema predominates, it is likely that edema formation in head injury is complicated, with time-dependent contributions of both vasogenic and cytotoxic mechanisms. Experimental evidence points to transient compromise of the blood-brain barrier occurring immediately after injury, with resultant vasogenic edema. Studies indicate early closure of the blood-brain barrier, after which cytotoxic, cellular edema predominates.^{198,261-263}

HYPEROSMOLAR THERAPY

Mannitol

Mannitol, an inert six-carbon alcohol of the corresponding sugar mannose, causes cellular dehydration by increasing serum osmolality. The use of mannitol in head-injured patients to lower ICP is based on two mechanisms of action of this drug: It establishes an osmotic gradient across the blood-brain barrier to reduce water content,^{264,265} and it causes cerebral vasoconstriction through rheologic effects that decrease blood viscosity and enhance CBF and MABP (see earlier section, “Viscosity”).^{245,266,267} This vascular mechanism of action has a strong, independent effect, such that CBF can be enhanced even when ICP is not substantially reduced.^{268,269}

With head-injured patients, mannitol is used in two clinical scenarios. The first is that of a comatose trauma patient with a surgical clot, when mannitol is given on the way to the operating room to buy time until emergent decompression is accomplished. Generally, higher doses of up to 1.2 to 1.4 g per kg can be given in this scenario.^{270,271}

The second clinical scenario is one of cerebral edema, when mannitol is given to control ICP. Unlike with its use for emergency surgical clots, there is no consensus on the optimal dosing regimen of mannitol in the ICU to manage ICP. Doses ranging from 0.25 g per kg to 1.0 g per kg may be effective. Mannitol can be given in response to high ICP, or it can be used prophylactically regardless of ICP, using serum osmolality as an end point of treatment,²⁷² although some evidence indicates that it is most effective when used in the presence of high ICP or low perfusion pressure.^{267,273}

Regardless of how mannitol is used, because of its osmotic diuresis, replacement of urinary water and electrolyte losses is critical, to avoid hypovolemia and hypotension. Mannitol typically is given as a bolus at a rate not to exceed 0.1 g per kg per minute in order to avoid hypotension.²⁷² Caution should be exercised in patients with a propensity toward congestive heart failure, because the early effects of bolus administration cause intravascular volume expansion.²⁷²

Mannitol can extravasate into the interstitium of the brain, with breakdown of the blood-brain barrier, which may be a cause of cerebral edema. This is thought to be less of an issue with bolus dosing as opposed to continuous infusion.²⁷⁴ Because of this particular concern with mannitol toxicity, many clinicians prefer to use the smallest doses of mannitol necessary, and to administer it only for proven intracranial hypertension.²⁷⁵

Another concern is renal failure, which is a rare complication of mannitol therapy. It is generally believed that the kidneys are at risk above a serum osmolality of 320 mOsm

per L^{276,277}; however, kidney damage may in fact be due to high serum concentrations of mannitol itself, as opposed to high serum osmolality. It is suggested that keeping the osmolar gap (measured serum osmolality minus calculated serum osmolality) below 55 mOsm per kg of H₂O may be better than using serum osmolality alone to direct mannitol therapy.^{272,277}

To summarize, mannitol therapy in the ICU is effective given as boluses for elevated ICP while keeping the patient normovolemic and hyperosmolar with an osmolar gap less than 55 mOsm per kg.

Furosemide, a loop diuretic, has some effectiveness for removing extracellular fluid from the brain. Although it does not work as fast as mannitol, furosemide commonly is used in conjunction with that agent because of a synergistic effect on ICP.²⁷⁸

HYPERTONIC SALINE

In many ICUs, hypertonic saline is being used with increasing frequency for the treatment of raised ICP in patients with traumatic brain injury.²⁷⁹ It is known that patients with hypotension after severe traumatic brain injury have twice the mortality rate of normotensive patients²⁸⁰; therefore, aggressive resuscitation with intravenous fluids is recommended in the guidelines for the management of patients with severe traumatic brain injury.²⁸¹ However, the real concern for the development of cerebral edema is reason enough to limit the amount of free water available to the injured brain during this early period. The use of hypertonic saline, both to increase mean arterial pressure and to decrease ICP, is a logical and promising approach to limit secondary injury and improve neurologic outcome.

The rapid infusion of a small volume of hypertonic solution originally was designed for the prehospital treatment of hemorrhagic shock,²⁸²⁻²⁸⁵ and a trial found a trend toward a reduction of ICP in a double-blind, randomized, controlled trial of prehospital fluid resuscitation using hypertonic saline in comatose and hypotensive head-injured patients (although no improvement in outcome was demonstrated).²⁸⁶

The rapid infusion of small volumes of hypertonic solution leads to an osmotic gradient that mobilizes parenchymal fluid into the vascular compartment,^{287,288} resulting in hemodilution, endothelial shrinkage, and improved blood flow in the microcirculation,^{289,290} as well as improved cardiac output.^{282,283,291} Hypertonic saline has been shown to reduce brain bulk and ICP²⁹²⁻²⁹⁵ and to be effective in lowering ICP both in bolus form and as a maintenance fluid.²⁹⁶⁻²⁹⁸

It is widely believed that the mechanism of action of both hypertonic saline and mannitol in reducing ICP is their hyperosmolar properties, although additional mechanisms are likely to be in play. Some authors have found hypertonic saline to be more effective than mannitol in selected patients.^{299,300}

Concerns about central pontine myelinolysis and acute renal failure appear to be unfounded on the basis of clinical experience; however, a rebound effect may occur in some patients.³⁰¹ A trial also reported no episodes of acute anemia or hypokalemia associated with 23.4% saline administration, nor were there any episodes of convulsions, congestive heart failure, or coagulopathy after the administration of hypertonic saline.²⁹⁹

In the United States, 3% sodium chloride is readily available. An initial dose of 1.5 to 3.0 mL per kg with a target for a serum sodium concentration of approximately 155 mEq per L is reasonable,²⁹⁵ although 23.4% saline has been shown to be safe and effective in the treatment of intracranial hypertension.²⁹⁹ As with hyperosmolar therapy for mannitol, it is important to maintain a normovolemic state at all times during treatment.

CEREBROSPINAL FLUID COMPARTMENT

CSF is produced mostly by the choroid plexus located in the ventricles. CSF flows from the lateral ventricles (first two ventricles) through the foramina of Monro into the third ventricle, and from there the fluid moves through the aqueduct of Sylvius to the fourth ventricle. From the fourth ventricle, CSF moves out of the ventricular system through the foramen of Magendie in the midline and the foramina of Luschka laterally. CSF then enters the subarachnoid space of the brain and spinal cord and circulates around the surface of the cerebellum and brainstem as it comes up through the tentorial hiatus, thus forming the basal cisterns. The clear and colorless fluid migrates over the cerebral hemispheres toward the midline, where, through a semiactive process, it is transported from the subarachnoid space into the superior sagittal sinus.

CSF is made at a continuous rate of approximately 0.3 mL per minute. With a total volume of approximately 150 mL (roughly 10% of intracranial volume), the entire CSF volume is replaced three times a day. A little less than one third of the total volume is in the ventricular system.

In severe head injury, CSF can be displaced out of the intracranial compartment as pressure differences between the superior sagittal sinus and the intracranial compartment increase (see Fig. 66.16). The spinal CSF compartment also is an important physiologic sink, and this contribution of CSF flow to ICP is another justification for nursing traumatic brain-injured patients with the head elevated.³⁰⁰

A standard way of managing the CSF compartment in the trauma patient is by draining CSF through an indwelling ventricular catheter (ventriculostomy). This has proved to be a relatively safe and effective tool in lowering intracranial volume and pressure, although ventricles in younger trauma patients commonly are smaller and harder to access and have less CSF to drain. Ventricular drainage is discussed further in Chapter 17.

SPECIFIC TREATMENT CONSIDERATIONS

CRANIECTOMY

Craniectomy is an alternative to the medical and direct surgical methods for reducing intracranial volume. This is a surgical strategy for managing a dangerous increase in intracranial volume by expanding the size of the intracranial compartment. The necessary expansion is accomplished by removing a large portion of the skull and opening the dura (see Fig. 66.13).

Intractable intracranial hypertension despite maximal medical therapy is associated with a high risk of morbidity

and death.³⁰¹⁻³⁰³ In one multicenter trial, an 86% mortality rate was found among patients whose condition failed to respond to an induced pentobarbital coma³⁰⁴—the last line of defense in medical management. Similarly, a significant relationship has been recognized between an ICP higher than 25 mm Hg and a poor outcome.³⁰⁵

Because of these ominous facts, craniectomy to increase the space available for the swollen brain has been used to lower ICP, although early outcome studies of hemicraniectomy yielded poor results.³⁰⁶⁻³⁰⁸ More contemporary experiences, however, have achieved better results. In 2006, Aarabi and colleagues reviewed 10 reports published since 1988, with a total of 323 patients treated with decompressive craniectomy for posttraumatic brain swelling and intractable intracranial hypertension, and calculated a collective mortality rate of 22.3%, with good outcomes in 48.3%, with the rest of the patients (29.4%) remaining severely disabled or vegetative. These results compared favorably with six previous reports in which the mortality rates ranged from 42% to 100% when ICP greater than 20 mm Hg remained refractory to medical management. Reported complications included subgaleal collections, which resolved over the course of weeks to months; delayed wound healing; bone flap resorption and infections; increased swelling and hemorrhagic contusions; and parenchymal lucencies, possibly due to ischemia.*

In addition to the demonstrated improvement in outcome, contrast-enhanced ultrasonography has been used to assess cerebral perfusion after decompressive craniectomy and found an average fivefold improvement in microvascular blood flow.³¹⁹ A technical point worth emphasizing is that a decompressive craniectomy must be sufficiently large in order to be helpful.³²⁰

MANAGEMENT OF INTRACRANIAL HYPERTENSION

Acute, severe traumatic brain injury is a dynamic process with the potential for dangerous changes that can evolve over hours to days; therefore, all patients need to be observed closely. Ideally, ongoing assessment by neurologic examination should be at least hourly. In most patients with a GCS score of 8 or less, however, airway protection mechanisms will be impaired, necessitating intubation and, therefore, sedation, which makes an accurate neurologic assessment problematic. An ICP measuring device usually is needed at this point to adequately monitor the patient, in lieu of a reliable examination (see Chapter 16 on ICP monitoring).

The medical management of intracranial hypertension in the ICU generally occurs after surgical decompression of hematomas causing unbalanced forces, or in patients without a surgical lesion. This management strategy generally is divided into tiers of therapy. The first tier is sedation, analgesia, and intubation without hyperventilation, keeping the head elevated and the neck straight and uncompressed. The routine use of paralytics may increase the risk of pulmonary complications; therefore, muscle relaxants should be used for ICP control when sedation is inadequate.³²¹ If

*See references 10, 217, 287, 301, 305, 309-318.

ICP exceeds 20 mm Hg³²² despite these maneuvers, moving to the next level of care is indicated, which includes CSF drainage if a ventriculostomy is being used, mannitol, or hypertonic saline. Beyond the first 24 hours, mild hyperventilation to keep P_{CO_2} in the mid-30s can be used. Throughout the clinical course it also is necessary to maintain an adequate CPP of at least 60 mm Hg by ensuring normovolemia and a safe MABP. If ICP is refractory to these treatments, the next step is use of decompressive hemicraniectomies or barbiturate coma (or both). Historically, surgical decompression has been reserved as a radical, end-of-the-line treatment after the patient has failed to respond to burst suppression barbiturate coma; however, craniectomy is moving up in the treatment algorithm of most centers (Fig. 66.20).

When ICP goes up, it is important to understand why and then try to correct the underlying problem if possible. In any given head-injured patient in whom the brain has lost its buffering capacity, with resultant poor compliance, small increases in intracranial volume can cause a significant rise in pressure. When ICP rises, CPP goes down. This usually will result in a decrease in CVR and vasodilation, with its attendant increase in cerebral blood volume and increase in intracranial volume. This of course leads to a further increase in ICP, and the cycle perpetuates itself. This is the mechanism of a plateau wave.²⁴⁵

In managing these patients, it is critical to try to determine the source of the problem. Perhaps the patient became hypovolemic and the blood pressure dropped, or a ventilator change caused hypercarbia or hypoxia. Maybe the patient is inadequately sedated or having an unrecognized seizure while pharmacologically paralyzed. The problem may be as simple as a high fever or a rigid cervical collar compressing the jugular veins. Whatever is driving this process must be corrected to break this dangerous plateau wave.

If the cause cannot be determined, a new CT scan may need to be taken, and therapeutic maneuvers should be employed to help turn things around, such as increasing

sedation, further head elevation, ventricular drainage, administration of mannitol or hypertonic saline, pressors when needed, and brief periods of gentle hyperventilation.

ANTICOAGULATION

It is intuitive that severe coagulopathy is associated with increased mortality after head injury.³²³⁻³³¹ Penetrating or blunt brain injury can be associated with the massive release of thromboplastin from neuronal tissue, thereby initiating the coagulation process, which evolves to an exaggerated fibrinolytic response and disseminated intra-vascular coagulopathy (DIC).³²⁴ This brain injury–induced coagulopathy may lead to significant secondary injury and delay the invasive monitoring necessary for the aggressive management of intracranial hypertension.³³² The criteria for the diagnosis of DIC include abnormal clotting studies, thrombocytopenia, low fibrinogen, and, in some cases, elevation in levels of products of fibrinolysis (D-dimer or fibrin degradation products).³²⁷ The DIC caused by head trauma is relatively common and frequently is detected by a prolonged prothrombin time and elevated international normalized ratio (INR). Its presence may be an indication for more intense clinical observation and follow-up CT scanning. An important component of DIC is coagulation; however, in the setting of active bleeding, anticoagulation is not indicated. The therapeutic focus is on hemostasis and replacement of diluted or consumed blood elements and components.³²⁸⁻³²⁹

Typical treatment of coagulopathy consists of fresh frozen plasma (FFP) administration; however, use of FFP can be problematic. This product takes time to administer, so that a relatively large volume of fluid may be given to a head-injured patient when it is important to avoid hypervolemia. Other concerns are the possibility of blood-borne disease transmission and, as reported in a rare case, transfusion-related acute lung injury. Another important issue is the variable effect FFP can have on brain injury–induced coagulopathy, such that it ultimately may fail to correct the coagulopathy.

Figure 66.20 **A**, Computed tomography (CT) image of a normal brain. **B**, CT scan of the brain of a patient with severe traumatic brain injury and medically intractable intracranial hypertension. Between the poorly controlled cerebral edema and the indwelling ventriculostomy, almost no cerebrospinal fluid can be identified on the scan, which shows complete obliteration of cortical sulci (*thick arrow*) and basal cisterns (*thin arrow*). Given the absence of shift, bilateral hemicraniectomies were required.

Preliminary data indicate that recombinant activated factor VII (rFVIIa) provides a rapid and successful correction of coagulopathy in head-injured patients.³²⁶ Originally developed for the treatment of hemophiliacs, rFVIIa also may be helpful in reversing the effects of anticoagulants and antiplatelet drugs.^{326,330-340} It is a vitamin K–dependent glycoprotein, similar to the human plasma-derived factor VIIa, which appears to promote hemostasis by activating the extrinsic pathway of the coagulation cascade.³⁴¹ Its mechanism of action is not fully understood but includes interaction with platelets or tissue factor to augment thrombin generation and platelet activation.^{330,332,334,335} Factor VIIa seems to be the bottleneck, the critical factor most depleted when patients are profoundly anticoagulated.³⁴² The use of rFVIIa to correct a coagulopathy before neurosurgical intervention was reported in 1998 in a hemophiliac patient with an EDH requiring craniotomy for evacuation.³⁴³ Although not specifically evaluated for use in DIC, rFVIIa has been administered to neurosurgical patients in whom DIC was likely to be present.^{329,338} Recombinant FVIIa has been used in the absence of hemophilia for neurosurgical emergencies such as EDH and SDH, SAH and intracerebral hemorrhage, tumor resection, and during placement of ICP monitors.^{333,336,338,340} A retrospective study found improved outcomes, without complications, when rFVIIa was used for coagulopathic patients requiring urgent neurosurgical intervention.³⁴⁴ The incidence of thrombosis after rFVIIa is low, but thrombosis is an extremely important potential complication^{334,338,339,345,346} and of particular concern in DIC.³²⁸ Precise dosing for conditions other than hemophilia has not been confirmed³³²; the Food and Drug Administration (FDA) has approved rFVIIa only for use in hemophilia; other uses are considered off-label.

In addition to the coagulopathy induced by a brain injury, neurosurgeons and intensivists often are faced with managing patients with traumatic intracranial hemorrhage who are pharmacologically anticoagulated. The use of these drugs is expected to increase as the population ages.³²⁹ These patients must have normal coagulation rapidly restored to prevent further bleeding and to make surgical intervention possible. One of the more common drugs encountered in clinical practice is warfarin; a typical scenario is one in which an elderly patient on warfarin sodium (Coumadin) falls and hits her head. It takes about 4 days to normalize coagulation if warfarin is stopped. With vitamin K, full reversal begins 4 to 6 hours after administration and takes about 24 hours to lower the INR. FFP contains vitamin K–dependent factors, is rapidly effective, and is given intravenously. Recombinant factor VIIa also can be used to normalize coagulation in these patients.^{329,336,347,348}

In hospitalized patients on heparin, reversal occurs approximately 60 minutes after an intravenous infusion is stopped. If it needs to be reversed faster, protamine is recommended. Desmopressin also has been recommended to reverse the effects of heparin. Subcutaneous heparin is usually not reversed.³²⁹

With low-molecular-weight heparin (LMWH), a partial thromboplastin time (PTT) is variably altered and not a reliable measure of its effect. Reversal of LMWH effect with protamine is variable in humans.³²⁹

A common situation is the presentation of a head-injured patient on an antiplatelet agent such as aspirin or other

nonsteroidal anti-inflammatory drug (NSAID). Acetylsalicylic acid (ASA) inhibits platelet aggregation for the life of the affected platelet, which is approximately 10 days. This occurs even at the lowest dose of 81 mg per day. A period of 5 to 6 days typically is needed after stopping aspirin to replace approximately half of the circulating platelets (10% per 24 hours). The effect of ASA on platelets is complete and irreversible. If treatment is necessary, platelet transfusion is given to provide unaffected platelets as long as no ASA remains in the circulation. Desmopressin (DDAVP) may secondarily improve platelet adhesion to endothelial defects and is therefore also recommended to overcome aspirin-induced platelet dysfunction. Other NSAIDs have various anticoagulant effects. If significant NSAID use has occurred before a neurosurgical emergency, the same interventional strategy may apply. Data confirming efficacy in counteracting an anticoagulant effect, however, are not available.³²⁹

Other antiplatelet agents include adenosine diphosphate (ADP) and glycoprotein receptor-blocking agents. Clopidogrel and ticlopidine irreversibly alter platelet aggregation³⁴⁹⁻³⁵² through a mechanism that is additive to the antiplatelet effects of aspirin. The platelets are permanently affected; once the drug is stopped, recovery of normal platelet function requires about a week until new platelets are produced. Rapid correction requires platelet transfusion, and DDAVP also may have a beneficial, short-term effect.³²⁹

Abciximab, eptifibatide, and tirofiban are highly effective in generating 80% to 95% reversible inhibition in platelet aggregation.^{349,350,352-355} Stopping the medication allows return of normal platelet function in approximately 48 hours for abciximab and in 4 to 8 hours for the others. Platelet transfusion increases the proportion of unaffected platelets and is the primary intervention.³²⁹

Fibrinolytic and thrombolytic agents disrupt formed clots.³⁵⁵⁻³⁵⁷ These drugs have a prolonged half-life and frequently are used in combination with heparin or other agents to ensure continued therapeutic anticoagulation. Because circulating fibrinogen is decreased during thrombolysis, cryoprecipitate, a source of concentrated fibrinogen, is the basis for reversing treatment.³²⁹ Although these agents have well-recognized applications for cardiac³⁵⁸ and neurologic^{359,360} problems, their use generally is not seen in patients presenting with head injury.

Hypothermia also is known to cause and worsen coagulation abnormalities,^{332,361} the treatment for which is rewarming. Certain medical conditions also may affect coagulation, and therefore may be important as underlying factors in patients with a head injury. DDAVP increases the release of factor VIII and von Willebrand factor and is used to treat mild hemophilia A, von Willebrand disease, and chronic renal and liver disease, as well as acquired and congenital platelet disorders.^{361,362-365}

DDAVP has a significant antidiuretic effect and will increase free water reabsorption in the kidney, potentially leading to overhydration and hyponatremia. This may cause serious problems in a severely head-injured patient with cerebral edema, poor compliance, and high ICP.

Unintended, iatrogenic worsening of coagulopathy may result with use of hetastarch solutions, which may be administered to increase intravascular volume. These solutions

may lower von Willebrand factor levels and alter platelet function. Low-molecular-weight hetastarch preparations are available that may cause less severe changes; however, if the patient requires correction of a coagulation abnormality, these solutions should be avoided if possible.³⁶⁵⁻³⁶⁸

NUTRITIONAL SUPPORT

Replacement of 140% of resting metabolic expenditure in nonparalyzed patients and 100% resting metabolic expenditure in paralyzed patients using enteral or parenteral formulas containing at least 15% of calories as protein by the seventh day after injury is recommended.^{3,369}

ROLE OF STEROID THERAPY

On the basis of class 1 evidence originating from a prospective randomized trial comparing dexamethasone and placebo in 300 head-injured patients, dexamethasone was found to be ineffective in improving outcome or reducing ICP in patients with severe brain injury.^{3,312} Methylprednisolone, when given in high doses to moderate and severe head-injured patients, is associated with increased mortality.³⁷⁰ Therefore, the use of steroids is not recommended in their management.

CONCLUSIONS

The management of traumatic brain injury will remain for the foreseeable future a major medical and surgical challenge. Despite concentrated basic research directed at elucidating the metabolic factors that mediate the transition from primary to secondary tissue damage, nothing has been found that might have clinical efficacy. As the percentage of the population older than 70 years of age continues to rise, ICU physicians will face an ethical dilemma when dealing with brain hemorrhages in this age group. Subdural hematoma in an 86-year-old with mild dementia on warfarin sodium (Coumadin) for atrial fibrillation is becoming one of the most common presentations in an active trauma center. At present, intensivists are left with the application of best protocol-driven critical care management, supported by a high index of suspicion for surgically correctable lesions, the judicious use of decompressive hemicraniectomy, and a societal commitment to protective and preventive programs.

KEY POINTS

- The management of severe head injuries remains a major challenge to neurosurgeons.
- The time from injury to surgery must be as short as possible to minimize the secondary manifestations of serious brain trauma.
- Hyperventilation, although very effective in reducing high intracranial pressure (ICP), must be used judiciously; otherwise, it may become more harmful

KEY POINTS (Continued)

- than helpful. Glucocorticoids have no significant therapeutic benefit in managing severe head injuries.
- A simple-to-use and highly predictable neurologic status scoring system, the GCS, has enabled meaningful multidisciplinary communication from the accident scene through intensive care and beyond, resulting in efficient and timely triage and treatment of these patients.
- Mannitol is used in head-injured patients to lower ICP. This drug exerts its beneficial effect through two mechanisms of action: It establishes an osmotic gradient across the blood-brain barrier to reduce water content, and it causes cerebral vasoconstriction through blood flow dynamic effects that decrease blood viscosity and enhance cerebral blood flow and mean arterial blood pressure.
- The use of hypertonic saline to increase mean arterial pressure and decrease ICP is a logical and promising approach to limit secondary injury and improve neurologic outcome.
- Craniectomy can be used to increase the space available for the swollen brain, thereby lowering ICP.

THE REHABILITATION PHASE

INTRODUCTION

Patients suffering major burn injuries present unique challenges in both the types and magnitude of management problems. Fluid resuscitation, pulmonary dysfunction, metabolic stress, and infections complicating burns may surpass similar problems in other intensive care unit (ICU) populations, and treatment is further complicated by abnormal drug pharmacology, severe pain, and psychosocial stress, all superimposed on the need for multiple major surgical procedures and prolonged rehabilitation.

This chapter will review the critical care management of burned adults. It will be apparent that in many areas existing literature is neither comprehensive nor rigorously “evidence-based.”¹ In providing a rationale for treatment, therefore, it is often necessary to extrapolate from studies in other disorders, particularly trauma. This may or may not be valid, particularly in such “burn-specific” areas as fluid resuscitation, inhalation injury, and nutritional support. These issues will be discussed as they arise, but readers will need to interpret this information for themselves.

INCIDENCE AND SURVIVAL FROM BURN INJURY

The incidence of burn injury has declined in the United States throughout recent decades. From the 1960s to the early 1990s, reported burns decreased from 10.2 to approximately 4.2 injuries per 1000 Americans annually, or about 1.25 million injuries²; hospitalizations decreased from over 90,000 to approximately 52,000/year; and deaths decreased at least 40%, from 9000/year to 5500/year. These trends are likely to continue.

Simultaneously, survival from burns has improved dramatically. During World War II, burns of 40% total body surface area (TBSA) produced a 50% mortality rate; today a similar mortality rate is seen with burns of over 80% TBSA.³ Survival rate is lower—though still improved—for the elderly, and even higher for children and young adults.⁴ These accomplishments are due to cumulative advances in fluid resuscitation, critical care, nutrition, surgery, and skin substitutes. However, it has been the organization of specialized burn centers around a consolidated team of experts that has made this success possible.⁵

Burn survival has been repeatedly shown to correlate with three major factors: patient age, burn size, and the presence of inhalation injury. Pulmonary damage from smoke inhalation is itself a serious injury, and can be as much as double the mortality rate from cutaneous burns alone.^{3,5} Ryan and colleagues found that burn size 40% TBSA or greater, age 60 years or older, and inhalation injury contributed to the mortality rate in a stepwise manner; patients with all three had a mortality rate of 90% (Table 67.1).⁶

This experience has two important implications for current and future burn treatment. First, mortality risk for many patients is now so low that almost no injury is too large to preclude survival. The decision to intentionally withhold treatment is now rare and is based on predicted quality of life rather than predicted fatality itself. Second, it has necessitated unprecedented research and interest on the rehabilitation of patients who increasingly survive catastrophic injuries. Functional outcomes of burn treatment, including quality of life and return to work, are now the most relevant measures of successful care for all patients.^{7,8}

However, the decline in burns has had other unintended consequences, which create challenges to the provision of effective burn care in many areas. As burns have decreased, so has the number of burn centers in the United States. There are now over 25% fewer burn centers than in 1970⁹; only 60 facilities in the United States are currently verified by the American Burn Association (ABA) and American College of Surgeons (ACS).¹⁰ This reduced number limits access to specialized burn care for many Americans. For the same reason, the experience of most physicians with even basic burn care has been dramatically reduced; many U.S. doctors—even surgeons—receive little or no burn training. As a result, important errors in initial burn assessment are made commonly by primary care providers,¹¹⁻¹³ leading to significant under- or (mostly) overtriage, care that is sometimes inadequate, and further stress on the few remaining centers, which now must cover larger referral areas.^{14,15}

PATHOPHYSIOLOGY OF BURNS

Although the term *burn* strictly denotes injury caused by heat from flames and scalding liquids, other agents including chemicals, electric current, ionizing radiation, and friction produce nearly identical coagulative necrosis of tissues. The magnitude of such injury depends on the intensity of the source (temperature, voltage, pH, etc.) and the duration of contact, and the clinical severity of a burn is a function of the depth and extent of injury; these factors determine what skin structures are destroyed, the magnitude of response, and the ability of the wound to heal. Accurate assessment of burn wounds is essential in determining appropriate treatment and in predicting outcome.

The outermost *epidermis* of the skin is a thin layer of metabolically active cells that provides a specialized barrier to moisture, bacteria, and chemicals. Burns limited to the epidermis display redness and mild pain without blisters. The underlying *dermis* is much thicker, containing large amounts of structural proteins, which provide strength and flexibility to the skin. Burns extending into the dermis (second-degree, or partial-thickness burns) can vary greatly in appearance and severity. Superficial dermal burns are red, painful, and moist, with prominent fluid-filled blisters, but coagulative necrosis of deeper injuries effectively seals off the skin surface, producing a dry wound. Hair follicles and sweat glands lined with epidermis penetrate through the dermis and serve as a source of epidermal regeneration as partial-thickness injuries heal. Full-thickness or third-degree burns destroy the entire dermis. Such injuries may be a variety of colors, but are invariably dry and relatively insensate. The coagulated dermis is constricted and rigid; as fluid accumulates beneath it, tissue pressure can increase to a dangerous degree, causing vascular compromise and compartmental compression (see later).

Cutaneous injury generates intense inflammation with protean systemic manifestations that persist even after wound coverage is attained. Immediately following injury,

Table 67.1 Risk Factors for Death from Burn Injuries*

No. of Risk Factors	Age >60 yr	Burns ≥40% TBSA	Inhalation Injury	No. of Patients	No. of Deaths	Mortality (%)
0	No	No	No	1314	3	0.2
1	No	No	Yes	112	5	4
1	No	Yes	No	31	1	3
1	Yes	No	No	75	4	5
2	No	Yes	Yes	79	21	27
2	Yes	No	Yes	30	12	39
2	Yes	Yes	No	1	0	0
3	Yes	Yes	Yes	22	21	95
TOTALS				1665	67	4.0

*This table indicates the three risk factors universally accepted to affect burn patient mortality rate, their prevalence, and relative contribution to mortality rate. These data are similar to those from many modern burn centers. Note that overall mortality rate is only 4% and that most patients are relatively young and have limited burn wounds, placing them at little risk of dying.

TBSA, total body surface area.

Adapted with permission from Ryan CM, Schoenfeld DA, Thorpe WP, et al: Objective estimates of the probability of death from burn injuries. *N Engl J Med* 1998;338(6):362-366. Copyright ©1998, Massachusetts Medical Society. All rights reserved.

release of inflammatory mediators causes widespread loss of capillary integrity and depletion of intravascular volume, as well as depressed myocardial contractility, increased peripheral vascular resistance, and systemic hypoperfusion. This shock state can be rapidly lethal, but with adequate support, hemodynamic stability is restored within 24 to 48 hours and is thereafter characterized by increased cardiac output and decreased vascular resistance. This process is fueled by a cascade of local and systemic inflammatory mediators and includes sustained release of epinephrine, cortisol, and glucagon, which generate hypermetabolism, autocannibalism of body protein stores, and glucose intolerance, which persist well into rehabilitation (see “Metabolic Support and Gastrointestinal Management,” later).

An even more obvious consequence of burn injury is the burn wound itself. Burned skin quickly accumulates a

coating of tenacious *eschar* comprising dried serum and necrotic dermis. Minor burn injuries can often be allowed to heal spontaneously as eschar sloughs and new epidermis emerges from deep appendages to cover the wounds. But the eschar of deep or extensive injuries is extremely susceptible to infection, which has historically been a frequent cause of death. Prompt removal of eschar and coverage with intact skin is essential to control sepsis, ameliorate inflammation, reduce scarring, and optimize functional long-term outcomes. This is a major goal of early burn treatment.

ACUTE CARE OF THE BURNED PATIENT

Acute burn treatment can be divided into four phases, which are outlined in [Figure 67.1](#). *Initial assessment* is the process of stabilizing the acutely injured patient, treating

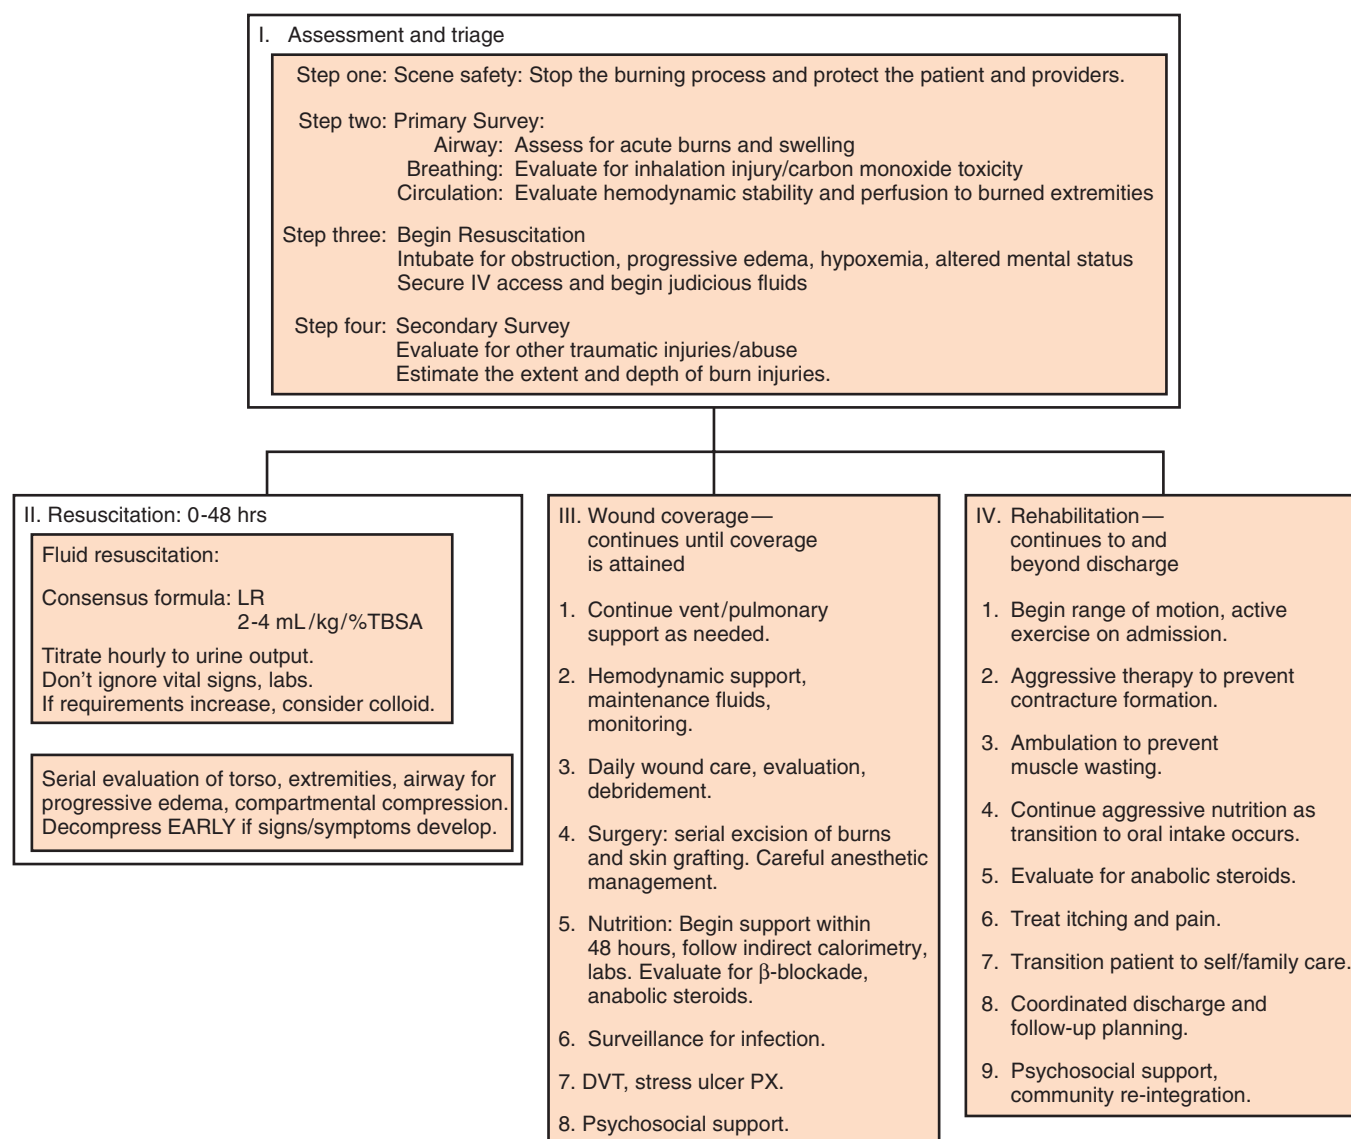

Figure 67.1 Schematic representation of acute burn treatment. Initial assessment and triage should follow the principles of advanced trauma life support, but particular attention must be paid to burn-specific conditions, including protection from additional injury and the presence of inhalation injury, acute edema formation, and major fluid requirements. Following this immediate care, ongoing burn treatment consists of acute fluid resuscitation, wound coverage, and rehabilitation. These phases are shown in overlapping boxes to indicate that, even though the importance of each varies as burn care proceeds, they are often performed simultaneously, and consideration of the importance of each should be borne in mind throughout the course of treatment. See text for additional details.

immediate life-threatening injuries, and preparing for inpatient care. The first 48 hours following injury constitute *acute resuscitation*, focused on initial assessment, airway support, and fluid replacement. The *wound coverage* phase then ensues, in which the major goal of treatment is surgical excision and closure of burn wounds. Ventilator management, metabolic support, control of infection and pain, physical therapy, and other supportive measures are essential adjuncts during this period. The goals of the final *rehabilitation* phase include scar control, optimizing function, and return to independent living. This period can last for months and continue long past discharge. Obviously these phases overlap: discoveries made during initial assessment may require prolonged management; many units begin surgical excision even before resuscitation is completed, and several aspects of rehabilitation—physical therapy, psychosocial support, nutrition, etc.—should start essentially at the time of injury.

INITIAL ASSESSMENT

Initial assessment of burn victims should follow the universally accepted protocol of the American College of Surgeons' Advanced Trauma Life Support (ATLS) course.¹⁶ In doing so, attention must be paid to several burn-specific issues, but it must be remembered that other types of trauma or preexisting conditions can always be present, emphasizing the importance of systematic patient evaluation.

SCENE SAFETY: STOP THE BURNING PROCESS

Though many burned patients receive appropriate on-scene care from first responders, remember that patients can suffer ongoing injury from smoldering clothing, caustic chemicals, and the like. Initial assessment of every patient should begin by assuring that the patient and care providers are protected from further harm. Awareness of the threat of terrorist incidents or mass casualties mandates that these principles be practiced consistently.

THE PRIMARY SURVEY AND INHALATION INJURY

In burn patients, assessment of airway, breathing, and circulation must include evaluation for signs and symptoms of inhalation injury. Carbon monoxide (CO) poisoning and asphyxia cause the vast majority of scene and emergency room fatalities, and up to 80% of fire-related deaths.^{17,18} Inhalation injury and its management are covered in Chapter 48.

Inhalation injury should be suspected in all patients exposed to flames or smoke, especially if the patient was unconscious or trapped in a closed space. Physical findings include facial burns, singed nasal hairs or eyebrows, wheezing or stridor, carbonaceous sputum, hoarseness, and anxiety. These findings should alert the examiner to the possible need for airway support.¹⁹

Inhalation injury is classically considered to consist of three distinct entities: CO poisoning, upper airway injury, and lower airway injury (the “true” inhalation injury). Although patients can frequently present with a

combination of all three problems, this classification is worthwhile because of the different pathologic processes and time courses with which these injuries present.

CARBON MONOXIDE POISONING

CO is a product of incomplete combustion, and its highest concentrations occur in indoor fires, where its effects may be amplified by flame-induced oxygen depletion.²⁰ CO displaces oxygen binding, producing systemic hypoxia despite normal oxygen tension. The most common symptoms are mental status changes, varying from headache to coma, which can present without burn injuries or respiratory distress and be overlooked easily. Classic “cherry red cyanosis” appearance is absent in many victims or can be obscured by soot or burns. Importantly, pulse oximetry is inaccurate in the presence of CO. Direct measurement of carboxyhemoglobin concentration should be performed but should never delay treatment. Patients are at greatest risk on presentation, and immediate application of oxygen is often definitive. As reviewed in Chapter 48, the use of hyperbaric oxygen for acute CO poisoning is controversial; it should probably be reserved for severe cases with neurologic compromise, when its use will not interfere with other essential components of acute burn care.

Smoke contains many other toxic chemicals, including cyanide. Cyanide poisoning has been documented in burn victims and does not always correlate with CO exposure.²¹ Because blood levels cannot be obtained immediately, empiric treatment using cyanide antidote kits has been advocated in patients with unusually severe acidosis or shock.²² The recent availability of hydroxocobalamin as a cyanide antidote, which has few side effects, has led to both renewed interest in the treatment of cyanide toxicity and aggressive marketing of the drug. However, a recent review points out that confirmed cases of significant cyanide poisoning following smoke exposure are rare.²³ At present, treatment of suspected cyanide toxicity in acutely burned patients is controversial, and indications are unclear.²⁴ High-flow oxygen coupled with aggressive resuscitation and cardiovascular support remain the mainstays of treatment.

UPPER AIRWAY INJURY

Patients with extensive or deep burns to the face, or who have breathed substantial quantities of hot gases or soot, are at risk of airway occlusion from progressive pharyngeal or supraglottic edema and facial swelling. This swelling can occur even without flame injury in children with scalds or severe chemical burns. Edema formation can be extremely rapid and progress for at least 24 hours. Patients must be followed serially, and intubated early and electively if evidence of progressive airway compromise occurs. [Figure 67.2](#) illustrates such a case.

INDICATIONS FOR INTUBATION

Awareness of the potential for acute airway compromise following burn injury has led to a liberal attitude toward intubation that is probably appropriate. “When in doubt, intubate” expresses many physicians’ attitude toward this problem. However, this dictum has sometimes led to indiscriminate and unnecessary intubation of patients with even minor facial burns.²⁵ The presence of inhalation injury does not mandate intubation, and airway compromise can be

Figure 67.2 This young man was burned playing with matches and gasoline, sustaining burns to 60% total body surface area, including his entire face. On presentation, he was alert and breathing comfortably. Arterial blood gases (including carboxyhemoglobin) and chest x-ray findings were normal. Based on the extent and location of his injuries, elective nasotracheal intubation was performed. Six hours later, the patient displays massive facial edema. Eyes are swollen shut, and oral excursion is severely restricted. If he lost his endotracheal tube at this point, his airway could not be maintained. Note that the tube is tied around his head securely, not taped in position. He will need to remain intubated for at least 3 to 5 days until most of this edema resolves.

life-threatening even in the absence of inhalation injury. Indications for intubation, as in all trauma patients, are based on symptoms found on initial assessment, including altered mental status, refractory hypoxemia, and signs of impending airway obstruction including wheezing, stridor, dyspnea, and progressive facial swelling. Emergency tracheostomy or cricothyroidotomy, which should rarely be needed if intubation is performed in a timely manner, can be an extremely challenging procedure in the setting of massive head and neck swelling.

PULMONARY (“TRUE”) INHALATION INJURY

Exposure of the bronchi and small airways to toxic smoke causes chemical injury to the epithelium, which can progress to mucosal sloughing, mucous plugging, bronchiectasis, hypoxemia, and pneumonia. Clinical signs of this problem may be absent for up to 72 hours after exposure,

Figure 67.3 Bronchoscopic appearance of the carina of a man who was dragged unconscious from a burning house. Carbonaceous deposits are apparent in his trachea, and more extensively in the mainstem bronchi. This finding is diagnostic of inhalation injury.

and initial chest radiographs are usually normal.²⁶ Patients with immediate respiratory distress, stridor, or hypoxemia are much more likely to have upper airway injury. Even in the absence of symptoms, patients suspected of having inhalation injury require hospital admission and close observation. Fiberoptic bronchoscopy demonstrating carbonaceous debris, erythema, or mucosal sloughing is highly sensitive for diagnosis of inhalation injury and can facilitate immediate intubation if injury is confirmed²⁷ (Fig. 67.3). Inhalation injury is discussed further in Chapter 48.

BEGIN RESUSCITATION

Following quick initial assessment, intravenous resuscitation and other support should be initiated.

THE SECONDARY SURVEY

As resuscitation is beginning, a thorough head-to-toe examination is performed. Burn victims frequently suffer other trauma, which can be obscured by overlying burns (see later). Much of the subsequent care of the burn patient is based on assessment of the extent and depth of injury, including fluid resuscitation, nutritional requirements, surgery, and in extreme cases, the decision to provide aggressive treatment. For these reasons, the burn wound should be washed and thoroughly debrided and then documented as accurately as possible, preferably by an experienced clinician. Rough estimates of burn size are often made using the “rule of nines”; more accurate detailed documentation can be done using the Lund and Browder chart (Fig. 67.4). Computerized programs are also becoming popular, such as the Sage diagram (www.sagediagram.com). In evaluating smaller injuries, another useful rule is that the area of the patient’s palm (with fingers) equals about 1% of his/her TBSA.

BURNS AND MULTIPLE TRAUMA

The many mishaps that cause burns often cause other trauma as well. These situations can include explosions

LUND AND BROWDER CHART

Figure 67.4 The Lund and Browder chart is in widespread use in burn centers for diagramming and calculating burn extent and depth. The chart divides the body into small areas and gives the relative percent total body surface area for each area for different age groups. With a little practice, physicians can estimate burns quite accurately. To do so, evaluate wounds after they have been washed and debrided. Inspect each area carefully and attempt to distinguish between partial- and full-thickness burn wounds. Total burn size is calculated by adding individual body areas.

(blasts, falls, projectile wounds), electrocutions (tetany-induced fractures, falls), fires in motor vehicle or airplane crashes, and escaping fires (lacerations, falls). Combined burn/trauma injuries are particularly likely following assault or child abuse and should increase suspicion for such causes.²⁸

The combined mortality rates for burns and trauma appear to be at least additive compared to either injury alone.^{29,30} Thorough evaluation of all potential injuries according to ATLS guidelines is imperative and can be challenging in burn patients: the discoloration, pain, and swelling of burn wounds, for example, can conceal underlying fractures³¹; and burns of the torso or acute inhalation injury can obscure a pneumothorax or other injuries. For this reason, it is important not to focus too heavily on burn injuries in performing the secondary survey.

In addition, care should be provided by a multispecialty team with expertise in managing all injuries. Treatment of many traumatic injuries takes priority over definitive burn care and mandates immediate operation. Because fresh burn wounds are initially—and briefly—free of bacteria, laparotomy, craniotomy, repair of lacerations, and operative fixation of fractures should be performed immediately, and no later than 12 to 24 hours after burn.^{32,33} This approach will minimize risk of infections, permit early mobilization, and facilitate access to burn wounds for dressings and surgery. These interventions can be performed safely provided essential components of burn care—including airway support, temperature control, and aggressive fluid resuscitation—are instituted immediately and continued through surgery. Close coordination between the burn center and trauma center will optimize outcome for these patients.

THE RESUSCITATION PHASE

BURN SHOCK

Following initial evaluation, the primary focus of early burn treatment is fluid resuscitation. The goals of resuscitation are to support organ function while avoiding complications of over- or underadministration of fluid.³⁴ This task can be challenging given the huge fluid shifts and cardiovascular effects of acute burns. Development of effective protocols for resuscitation represents one of the major advancements in burn care in this century.

The magnitude of fluid shifts following a major burn can exceed those of any other injury. At the cellular level, burn injury immediately impairs membrane adenosine triphosphatase (ATPase) activity and reduces transmembrane potential,^{35,36} resulting in increased intracellular sodium and extracellular potassium concentrations, cellular swelling, and acidosis. Fluid resuscitation only partially corrects these abnormalities, which may require several days to resolve completely as local inflammation subsides.

These events present clinically as a profound inflammatory response, causing increased capillary permeability and massive tissue edema at the expense of intravascular volume. Immediate release of histamine and serotonin increase local perfusion, initiate capillary leakage, and potentiate vasoconstriction caused by massive catecholamine secretion.³⁶⁻³⁸

Tumor necrosis factor (TNF)- α produces myocardial depression and activates a number of other vasoactive mediators.³⁹ Prostaglandins, leukotrienes, oxygen radicals, products of platelet activation and coagulation, and a cascade of cytokines also contribute to these abnormalities.^{40,41} Alterations in local blood flow increase arteriolar tone and pressure and dilate postcapillary venules, causing local capillary perfusion to become less selective and increased, favoring extensive edema formation.

The forces that control transcapillary fluid flux are summarized in Starling's equation⁴²; their alterations in burn injury have been reviewed by Demling⁴³ (Table 67.2). The greatest edema formation occurs almost immediately within the wound, caused by near-total permeability to even very large (35 nm) molecules,⁴⁴ and permitting protein-rich plasma to pour into the interstitium.⁴⁵ Maximum protein extravasation occurs within the first hour of injury, and both its duration and magnitude are proportional to burn size.^{46,47}

Even after local capillary integrity normalizes within 8 to 12 hours, edema formation continues in unburned as well as burned tissues.⁴⁸ Depletion of intravascular proteins, further diluted by crystalloid resuscitation,⁴⁹ eliminates the oncotic pressure gradient (see $\pi_p - \pi_i$ in Table 67.2), which maintains intravascular volume. Hypoproteinemia alone can mimic burn edema, and infusions of colloid can almost completely prevent edema in unburned tissues.^{50,51} Progressive edema also alters the configuration of interstitial collagen and hyaluronic acid, which are normally densely coiled to limit fluid influx.⁵² Burn injury disrupts this “safety valve” configuration, increasing compliance, producing osmotically active molecular fragments, and generating negative (“sucking”) interstitial pressure⁵³ and extremely rapid fluid sequestration.⁴⁸ Though this gradient is neutralized within a few hours, compliance continues to increase as interstitial gel is hydrated, allowing liters of fluid to accumulate with little change in hydrostatic pressure⁵⁴ and permitting edema to persist for weeks following injury.

Cardiac output falls within minutes of injury, reaching 50% to 60% of normal within an hour, although systemic vascular resistance (SVR) increases dramatically. Both changes occur far faster than the depletion of intravascular volume^{45,55} and regardless of fluid resuscitation. Release of catecholamines and other vasoactive mediators clearly increases SVR, but the decrease in cardiac output is harder to explain. Researchers have long postulated the existence of a “myocardial depressant factor,”⁵⁶ though no such substance has been isolated. It seems more likely that cardiac output is impaired by the combination of increased SVR, volume depletion, and actions of TNF- α , endotoxin, and other chemicals. One clinically important side effect of capillary permeability is hemoconcentration—a marked rise in hematocrit as plasma is sieved out of the bloodstream into the interstitium—which increases blood viscosity and further impairs cardiac output.

Cardiac output begins to recover within a few hours of injury and requires 12 to 24 hours to normalize, even with vigorous resuscitation. SVR follows an opposite course, peaking quickly and then declining to near-normal within 24 to 48 hours (Fig. 67.5). Following these initial changes a chronic hyperdynamic circulation is maintained, with cardiac output persisting well above normal, and marked

Table 67.2 Starling Forces and Capillary Permeability*

Starling's formula: $Q = K_f (P_{cap} - P_i) + \sigma (\pi_p - \pi_i)$		
Symbol	Definition	Alteration in Burn Injury
Q	Net rate of fluid passage across the capillary membrane	Increased dramatically as a result of changes in all component forces
Kf	Filtration coefficient; consists of two components: The surface area of the capillary system Compliance of the interstitium	Increased as a result of increased local blood flow, perfusing more capillaries Increased owing to alterations in molecular configuration (see text)
Pcap	Capillary hydrostatic pressure	Increased as a result of arterial vasoconstriction
Pi	Interstitial hydrostatic pressure	Decreased secondary to changes in molecular configuration of the interstitium (see text)
σ	Reflection coefficient—describes the permeability of the capillary to macromolecules Ordinarily this is quite limited; a coefficient of 1.0 indicates that no protein can pass across the membrane; a coefficient of zero implies total permeability. For normal skin, this value is approximately 0.9.	Greatly increased permeability to even large molecules; in burned skin, this value approximates 0.3 This effect appears largely limited to burned tissues; generation of edema formation in nonburned tissues depends more on changes in colloid oncotic pressure and interstitial compliance.
π_p	Plasma colloid oncotic pressure Each gram of albumin generates approximately 4 mm Hg of oncotic pressure; normal π_p is 20 mm Hg.	Progressively reduced Most direct leakage of albumin is into burned tissues, but as this occurs, π_p is reduced systemically. This is further diluted by crystalloid resuscitation
π_i	Interstitial colloid oncotic pressure	Reduced slightly, but this effect is limited owing to changes in interstitial compliance
$P_{cap} - P_i$	The difference in hydrostatic pressure across the capillary membrane The greater the gradient, the more rapid the flow of fluid. Normal gradient is 10–12 mm Hg.	Increased owing to increased hydrostatic pressure; little or no increase in interstitial pressure
$\pi_p - \pi_i$	The difference in oncotic pressure across the capillary membrane	Reduced owing to dilution of plasma proteins; little change in interstitial pressure

vasodilation and decreased SVR often persisting even after wound coverage is attained.

FLUID RESUSCITATION OF BURN PATIENTS

Before World War II, patients with even moderate burns usually died within a few days because of progressive shock and renal failure. In 1942, surgeons Oliver Cope and Francis Moore designed the first formal resuscitation regimen to treat victims of the Coconut Grove nightclub fire, with substantial improvements in survival.³⁶ With continued refinements, today almost all patients can be resuscitated successfully, and renal failure complicating burn injury is rare. A host of formulas have been developed, almost all based on body weight and burn size, and utilizing various combinations of crystalloid and colloid solutions. The archetype and most widely used of such regimens is the Parkland formula, designed by Baxter.³⁵ He demonstrated that a volume of lactated Ringer's (LR) solution equal to 4 mL per kilogram body weight for each percent TBSA burned (4 mL/kg/%TBSA), given in the first 24 hours after injury, would maintain urine output of 50 to 70 mL/hour, replete blood volume, and restore cellular transmembrane potential and cardiac output in most patients. Half this

calculated volume is given in the first 8 hours after burn, the remainder over the next 16 hours. The intravenous rate is adjusted hourly to maintain urine output and is decreased gradually until a “maintenance” rate is reached at approximately 24 hours.

Maintenance requirements for burn patients are also increased due to ongoing evaporative and metabolic losses, and continued fluid support is essential even after resuscitation is complete. A popular formula to estimate these requirements is that developed by Warden.⁵⁷

$$\begin{aligned} & \text{24-hour maintenance fluid requirements} \\ &= \text{Evaporative water losses} + \text{normal insensible losses} \end{aligned}$$

In this equation,

$$\text{Evaporative water losses} = (35 + \%TBSA \text{ burn}) \times m^2 \times 24 \text{ hours}$$

$$\begin{aligned} \text{Normal insensible losses} &= (1500 \times m^2) \text{ per 24 hours} \\ m^2 &= \text{body surface area in square meters} \end{aligned}$$

This experience forms the basis of modern burn resuscitation. But despite widespread acceptance of the principles of fluid replacement, disagreement persists over almost every aspect of practical management, and the practice of
